The findings in the kidneys were identical with those described by Lucke⁴ as characteristic of "lower nephron nephrosis," a clinical and pathological syndrome that may complicate a variety of medical and surgical conditions. The syndrome frequently follows transfusion incompatibilities,⁶ but in the case presented above, manifestations of renal damage preceded transfusion. The syndrome may also follow intravascular hemolysis in malaria,¹⁰ severe burns¹¹ and sulfonamide-sensitive states.¹ The patient described above did not have malaria, nor was he burned. Other evidence of sulfonamide sensitivity was lacking. Necrosis of the lower nephron and the presence of pigment casts have also been described in a variety of liver diseases. Under such circumstances the renal pathology is usually referred to as cholemic or "bile" nephrosis. In the present case it seems likely that the renal lesions were secondary to the severe liver damage.

In that event the findings in the liver are not pathognomonic of any specific condition. They are, however, inconsistent with the lesions produced by sulfonamide sensitivity.¹² Except for the occasional case in which sensitivity develops, evidence of a hepatotoxic action on the part of any of the sulfonamides is highly questionable, a point empha-

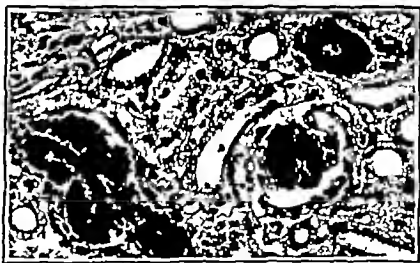

FIGURE 3 Section of a Kidney Showing Damage to Tubular Epithelium and Pigment Casts

hepatitis. Inclusion bodies of one sort or another have been described and produced in a great variety of non-virus conditions. Inclusions indistinguishable from those of yellow fever, for example, have been observed in liver cells of burned patients treated with tannic acid.¹⁶ Furthermore, the virus of herpes is not known to infect the liver of man or animal.

The patient, like all military personnel in the theater, had previously received attenuated yellow-fever-virus vaccine. At the time the fever treatments were being given, hepatitis was fairly prevalent among the troops. Whether "epidemic" and "serum" hepatitis are in reality the same disease has not yet been established. It has been amply demonstrated, however, that the serums of certain

persons at times harbor a hepatotoxic virus. Whether it can be activated by fever is at the moment unknown. Morphologically, except for the presence of inclusion bodies, the liver in the case discussed above bears many similarities to the pathology of infectious hepatitis described by Lucké¹⁷ and many others. From a clinical point of view, however, the hepatitis that follows fever therapy is as a rule less severe and of considerably shorter duration than the infectious hepatitis.

A more probable etiology for this form of hepatitis is to be found in high body temperatures per se. Although the critical temperature above which liver cells become irreversibly damaged is unknown and probably varies to a certain extent with the state of nutrition of the individual cells, there is evidence that this point is not far above those frequently encountered. King et al.² showed that the incidence of jaundice among patients receiving fever therapy was higher in a group whose temperatures were maintained at 106.6°F than in a group held at 106.0. More significantly, they noted that jaundice was particularly likely to occur if the temperature were allowed to rise for even brief periods above the former figure. Evidence also exists that the majority of patients receiving intensive fever therapy suffer some degree of liver damage, even though clinical jaundice fails to appear. The same authors showed that in a group of 40 consecutive cases a subclinical rise in serum bilirubin occurred in 75 per cent. Hippuric acid tests performed before treatment and repeated three days later showed a significant reduction in liver function in 12 cases. Wilson and Doan¹⁸ studied a similar group of patients and found a post-therapeutic rise in bilirubin and an increased retention of brom-sulfalein in each case, the degree and duration of fever were not recorded.

Although observations on animals subjected to experimental hyperpyrexia include no clinical or pathological effects exactly comparable to post-hypertherm hepatitis in man, changes in the liver have frequently been described. Hartman and Major¹⁹ placed dogs in a Kettering hypertherm cabinet and maintained their rectal temperatures between 107 and 110°F (41.7 and 43.3°C) for five to seven hours. The animals died or were sacrificed at intervals from one to seventy-two hours later. The predominant lesions were those of congestion and hemorrhage, but many livers showed extensive midzonal necrosis. Hall and Wakefield²⁰ maintained dogs at comparable temperatures by similar means. Lesions in the liver were limited to cloudy swelling, probably because the animals were examined too soon after exposure for more significant morphologic changes to have developed. Other investigators have raised the temperatures of animals by less pertinent means. Jacobsen and Hosoi,²¹ using high-frequency currents, maintained dogs for periods up to twelve hours with rectal temperatures

of 108 to 111°F (42.2 to 44.0°C). Most of the dogs died promptly, but some of the survivors showed focal necroses in the liver.

Rawlinson and Kellaway²² perfused cat livers with hot saline solutions and determined in the perfusate the concentrations of several cellular constituents. Their results indicate that liver cells are severely damaged by temperatures as low as 104°F (40°C) when maintained for six hours. Although the conditions of perfusion produced cellular damage, that which occurred at high temperatures was significantly greater than could be accounted for by a simple exponential increase in the rate of processes operating at body temperature.

Opportunity for studying the morphologic effects of high temperatures on the human liver does not occur often because hyperpyrexia usually brings death within a few hours or the patient survives. In prompt deaths signs of cerebral damage dominate the clinical and pathological picture. The liver may show "cloudy swelling." Occasionally, however, the survival period is adequate for clinical signs of liver failure and for morphologic manifestations of necrosis to develop. Wilbur and Stevens⁶ described a patient who lived for three days after a sunstroke during which the temperature had reached 110°F (43.3°C). Jaundice was present, and there was definite evidence of necrosis in the liver. Malamud, Haymaker and Custer²³ recently studied the pathology in 125 fatal cases of heatstroke among American troops. They found frank necrosis of the liver in only 12 cases, but all these occurred in patients who had survived for more than thirty hours, whereas the majority had died in less than twenty-four hours. Jaundice appeared clinically in some of the former group.

It is a common biologic observation that unicellular organisms differ widely in their sensitivity to heat, the critical temperature being, within limits, specific for the species. Among multicellular organisms certain highly differentiated cells are more sensitive to heat than less differentiated ones. In man there is evidence that hepatic cells, along with certain cells of the central nervous system, are among the first to be damaged by high temperatures. Although the part played by oxygen deficiency may be an intimate one, destruction of essential enzyme systems appears a more probable mechanism.

SUMMARY

Hepatitis, with or without jaundice, frequently complicates artificial fever therapy. Liver damage also occurs after other forms of hyperpyrexia.

The pathological findings in a fatal case of post-hypertherm hepatitis are presented. The liver showed extensive necrosis followed by regeneration.

Available evidence indicates that liver cells, in addition to certain cells of the nervous system, are particularly susceptible to damage by high fever.

SYPHILITIC PRIMARY OPTIC ATROPHY*

A Review of 54 Cases

SIDNEY LEVIN, M.D.,† LAURENCE D. TREVETT, M.D.,‡ and MILTON GREENBLATT, M.D.§

BOSTON

A FEW years ago the outlook regarding vision for patients with syphilitic primary optic atrophy was generally considered extremely poor, regardless of the type of therapy used. This attitude tends to persist in spite of the gratifying reports by Moore et al.¹ and others²⁻⁵ of unusually successful results with malaria treatment. One of the reasons for pessimism is that there is too often an excessive delay in starting treatment and that, as a result, optic atrophy may progress to blindness before adequate treatment is instituted. This delay often appears to be due to failure to make the proper diagnosis, lack of appreciation of the potential rapidity of progress of the disease or confusion regarding what constitutes adequate or proper therapy.

In view of these considerations we have undertaken to report an analysis of our cases of syphilitic primary optic atrophy.

MATERIAL

A series of 54 patients with syphilitic primary optic atrophy admitted to the Boston Psychopathic Hospital during the years 1921 to 1944 formed the basis of the investigation. The case records were reviewed and analyzed from the point of view of history, clinical findings and response of vision to treatment.

*From the Boston Psychopathic Hospital.

†Assistant in psychiatry, Harvard Medical School; assistant physician, Boston Psychopathic Hospital; assistant in neurology, Beth Israel Hospital.

‡Instructor in psychiatry, Harvard Medical School; consultant, Waverley Hospital.

§Instructor in psychiatry, Harvard Medical School; chief of laboratories and research, Boston Psychopathic Hospital.

The ages ranged from nineteen to sixty-two years. The age-distribution curve was essentially the same as that for patients with neurosyphilis in general, the maximum number of cases occurring between the ages of forty and fifty.

Of the 54 patients, 51 were males and 3 were females. There were only 2 Negroes in the series.

The duration from the occurrence of the primary syphilitic lesion to the onset of the visual loss (as judged by data available in only 20 cases) varied from ten to thirty-three years, with an average of twenty years.

FIRST MANIFESTATIONS OF NEUROSYPHILIS

The first clinical manifestations of neurosyphilis in cases that later developed optic atrophy were as follows:

SYMPTOM	No. of Cases
Gradual loss of vision	34
Lightning pains	3
Personality change	3
Difficulty in concentration or memory	3
Gastric crises	2
Pain in eyes	2
Diplopia	1
Ptoxis	1
Numbness on right side of face	1
Dysarthria	1
Urinary incontinence	1
Aphasia	1
Total	54

It is interesting that in 34 cases (63 per cent) the first manifestation was gradual loss of vision. It

is therefore apparent that every patient with the complaint of gradual loss of vision should have adequate investigation for central-nervous-system syphilis, even when other signs are absent

SEROLOGIC FINDINGS

In all but 1 case there was a report of the admission blood Wassermann or Hinton test, or both. In 39 cases blood Hinton tests were positive in 38 and doubtful in 1. In 19 cases blood Wassermann tests were positive in 13, doubtful in 2 and negative in 4. From these data it is apparent that a negative blood Hinton or Wassermann test is rare in untreated or inadequately treated cases of syphilitic primary optic atrophy.

PUPILLARY ABNORMALITIES

Of 51 cases in which the pupillary findings were recorded on admission, 49 showed pupillary abnormalities characteristic of neurosyphilis. Thirty-six patients were recorded as having Argyll-Robertson pupils, and 13 as having irregularity, inequality of the size of the pupils or absent light reaction.

DIAGNOSIS ON ADMISSION

After careful study of the case records, the following diagnoses were made: syphilitic primary optic atrophy alone, 15 cases, syphilitic primary optic

though visual acuity was markedly diminished. These findings are in contrast to those in trypan-blue optic atrophy, in which marked constriction of the visual fields often occurs and is usually accompanied by only slight loss of central vision.

DEVELOPMENT OF BLINDNESS*

In 43 cases in which data were available, the onset of visual loss was bilateral in 11 and unilateral in 32. Of the latter group, 16 cases began with involvement of the right eye and 16 with involvement of the left eye. Cases with unilateral onset, if untreated, usually developed involvement of the second eye within a few months. In untreated cases, however, optic atrophy occasionally remained unilateral for longer periods, the maximum duration being three years.

Untreated cases showed widely differing rates of progression. In the most rapidly progressive case complete blindness developed bilaterally within twenty-two days. The patient with the slowest progress, after seven years without treatment, had visual acuity of 10/100 in one eye and blindness in the other. One of the notable trends was the rather frequent development of blindness in both eyes within a twelve-month period, emphasizing the need for intensive early treatment.

TREATMENT BEFORE ONSET

In this series treatment prior to the development of optic atrophy was inadequate, permitting the hypothesis that visual involvement might have been prevented had more active measures been used. Only 15 patients (28 per cent) received any treatment prior to the development of optic atrophy. In these cases, chemotherapy alone was employed, consisting usually of only a few arsenical and bismuth injections. No patient in the series received fever treatment before the onset of optic atrophy.

Ten patients who had been fortunate enough to receive chemotherapy were given this treatment two to twenty years before the development of any evidence of optic atrophy. Five patients, however, developed the first signs of optic atrophy while receiving a course of routine antisyphilitic treatment. Therefore, syphilitic optic atrophy may begin and progress in some persons even though active chemotherapeutic measures are being used. In other words, chemotherapy is no guarantee against the development of optic atrophy.

EFFECT OF TREATMENT

Of 43 patients who were not totally blind when treatment was started, 27 were followed for two years or longer after treatment had been instituted. The average duration of follow-up study in these cases was seven years.

Figure 1 shows the superiority of fever therapy as compared to chemotherapy in these cases. Of

TABLE 1 Degree of Tabetic Involvement in Cases with Tabetic Features

INVOLVEMENT	NO OF CASES	NO OF CASES WITH LIGHTNING PAINS	NO OF CASES WITH TABETIC BLADDER	NO OF CASES WITH HISTORY OF GASTRIC CRISES
No ataxia—absence of tendon reflexes in lower extremities	15	4	2	3
Slight to moderate ataxia or positive Romberg sign	10	6	1	0
Marked ataxia	0	—	—	—

atrophy with tabes, 20 cases, syphilitic primary optic atrophy with general paresis, 14 cases, and syphilitic primary optic atrophy with taboparesis, 5 cases.

In 19 cases there was a paretic element, whereas in 25 there was a tabetic element. Our experience that optic atrophy is found much more frequently in association with tabes than with general paresis coincides with the reports of others.¹ Optic atrophy occurs more commonly, however, in association with general paresis than may be generally appreciated.

An analysis of the degree of tabetic involvement in the 25 cases with tabetic features is presented in Table 1. It was observed that the tabetic picture was essentially one of a mild degree, none of the cases showing marked ataxia.

VISUAL FIELDS

In general, the visual fields showed irregular constriction, which was usually of moderate degree even

*In this study an eye was considered blind if the visual acuity was 1/200 or less.

the 11 patients treated only with chemotherapy,* 6 (55 per cent) were blind on follow-up study of two years or longer. Of the 16 patients treated with fever therapy in addition to chemotherapy, only 2 (13 per cent) were blind on follow-up examination two years or more after treatment. In these 16 cases, fever therapy was usually followed by chemotherapy for one year or more. In 4 of the 16 cases, fever was artificially induced. The remaining 12 patients received malaria treatments, the number of chills varying from five to seventeen. The series of cases is too small to determine whether treatment with malaria was superior to treatment with artificial fever. It is interesting, however, that none of the 4 patients treated with artificial fever were found to be blind on follow-up study.

In general, the cases treated with chemotherapy had been of a less rapidly progressive variety prior to treatment than those chosen for fever therapy. It is also worth noting that in all 5 patients whose visual loss was arrested by means of chemotherapy alone the optic atrophy was essentially unilateral, on follow-up study all were found to be blind in one eye but to have little or no visual loss in the other. Moore¹ has stressed the fact that patients in whom the atrophic process is still unilateral respond best to treatment. These 6 cases, therefore, comprised a selected group of patients who were most suitable for treatment and in whom chemotherapy alone was apparently sufficient to prevent blindness in the eye showing little or no involvement. One is not justified, however, in recommending chemotherapy alone for such cases because in similar cases treated with chemotherapy follow-up study revealed complete blindness in both eyes.

In the entire series there were only 2 cases in which vision improved after treatment, and in both, the treatment had consisted of intensive malaria therapy followed by chemotherapy. In 1 case, immediately prior to the onset of treatment, the patient was blind in the right eye and had 20/100 vision in the left, four years later visual acuity was found to be 20/200 in the right eye and 20/30 in the left. In the other case, immediately before treatment, the patient was blind in the left eye and had 20/40 vision in the right, but three months later visual acuity was found to be 20/200 in the left eye and 20/20 in the right. It is not to be expected, however, that therapy will improve vision but that, with good fortune, vision will not be further impaired.

CEREBROSPINAL-FLUID FINDINGS

The cerebrospinal-fluid findings were classified according to severity as Group I, II or III (the last being the strongest and equivalent to the so-called "paretic formula"), in accordance with the classification of Moore.¹ Analysis of the first cerebrospinal-fluid findings recorded after the onset of syphilitic primary optic atrophy revealed that 41

patients (76 per cent) had Group III fluids whereas 13 had Group II fluids. Of the latter, 11 patients (85 per cent) had received treatment during the interval between the onset of the optic atrophy and the examination of the fluid. Of the 41 patients with Group III fluids, however, only 19 (46 per cent) had received treatment during the interval between the onset of the optic atrophy and examination of the fluid. These findings indicate that, in general, syphilitic primary optic atrophy is accompanied by

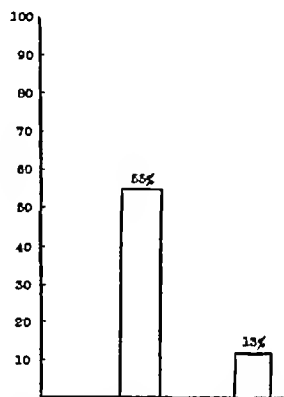

FIGURE 1. Results of Treatment of Syphilitic Primary Optic Atrophy by Means of Chemotherapy as Compared to Fever Therapy Combined with Chemotherapy, on Follow-up Study of Two Years or Longer.

strongly positive cerebrospinal-fluid findings unless antisyphilitic treatment has been started.

A further study was made of the cerebrospinal fluid in cases in which, as a result of treatment, optic atrophy had become definitely arrested for two years or longer (from two to fifteen years). There were 11 such cases, in 10 of which the cerebrospinal fluid had been examined during the six months following arrest of the optic atrophy. Only 1 of these patients had a Group III fluid, 3 a Group II fluid, 5 a Group I fluid and 1 a normal fluid. In the 9 cases with positive cerebrospinal-fluid findings the fluids later became negative with continued treatment (from nine months to about seven years). There was only 1 case in which visual loss was progressive after the cerebrospinal fluid had become negative. Since this patient was a diabetic, aged sixty years, the question whether the progression of visual loss was due to diabetic retinopathy rather than syphilitic primary optic atrophy remained unanswered.

The above data indicate that, in general, syphilitic primary optic atrophy becomes arrested before the cerebrospinal fluid becomes normal and that, when

*Four patients received intrathecal or intracisternal treatment in addition to routine chemotherapy.

the optic atrophy becomes arrested, the cerebrospinal-fluid findings usually fall in Group I or II

DISCUSSION

One of the most striking findings was the high incidence of Group III cerebrospinal fluids (paretic formula) in cases of syphilitic primary optic atrophy, even though many of the patients had received some treatment before examination. These findings support the histologic studies of Bruetsch,⁴ who states that "the pathologic basis of syphilitic optic atrophy is more like the process of dementia paralytica than of tabes," and remarks further that his findings uphold the anatomic studies of Leri,⁵ Stargardt⁶ and Richter⁷ that the primary lesion in syphilitic atrophy of the optic nerve is a peripheral and interstitial neuritis, which is followed by a slow, secondary degeneration of the nerve fibers. Many writers on this subject have been so fascinated by the term tabetic optic atrophy that they have overlooked this important conclusion of the early workers or have become confused by the many different opinions expressed on the pathogenesis of optic atrophy.

This point of view is in contrast to that previously expressed by Moore and Woods⁸ that the pathogenesis of syphilitic primary optic atrophy, which is often associated with tabes dorsalis, is identical with that of tabes dorsalis itself.

Indirect evidence in support of the conclusions of Bruetsch is found in the extensive perimetric studies of Sloan and Woods,⁹ who observed that the lesion responsible for syphilitic atrophy of the optic nerve and visual-field defects lies in the optic nerves rather than in the chiasm or posterior to it and is probably a peripheral and interstitial neuritis associated with secondary degeneration of the nerve fibers.

In view of the strongly positive cerebrospinal-fluid findings in syphilitic primary optic atrophy one might anticipate that these patients would require at least as intensive treatment as patients with general paresis. This appears to be true, and since blindness may develop rapidly, it is our opinion that all these patients should receive the most intensive treatment available as early as possible in the course of the disease, in the hope of preventing further damage to diseased nerves and thereby of preserving useful vision. In a review of our cases it became apparent that several cases had progressed to complete blindness without treatment and that in many others intensive treatment had been delayed or lacking.

Our favorable results with malaria therapy support the findings of Moore,¹ who reported that of 32 patients receiving malaria therapy, only 14 per cent were blind at the end of two years.

Unfortunately, we had too few patients treated with artificial fever to be able to evaluate its effectiveness adequately. In the 4 cases treated, how-

ever, the results were satisfactory. When these cases are added to those of Menagh,¹⁰ who obtained a satisfactory outcome in 4 of 6 cases so treated, Culler and Simpson,¹¹ who obtained satisfactory results in 13 of 16 cases, and Neymann and Osborne,¹² who obtained a satisfactory response in 4 of 6 cases, one is left with the impression that artificial fever is definitely effective in syphilitic primary optic atrophy.

SUMMARY

In 54 patients with syphilitic primary optic atrophy, seen at the Boston Psychopathic Hospital between 1921 and 1944, the first manifestation of neurosyphilis was usually gradual loss of vision.

Although syphilitic primary optic atrophy occurs most frequently in association with tabes, as a rule the tabetic features are mild.

Some abnormality of the pupils characteristic of neurosyphilis is almost always present.

A negative blood Wassermann or Hinton test is rare in untreated or inadequately treated cases.

Syphilitic primary optic atrophy is, in general, accompanied by a strongly abnormal cerebrospinal fluid (Group III) characteristic of the paretic formula. This finding is consistent with the studies of Bruetsch, in which the pathologic basis of this disorder was found to be more like the process of general paresis than that of tabes.

Syphilitic primary optic atrophy may respond well to fever therapy provided that treatment is started before useful vision is lost. Of 16 patients treated with artificial fever only 2 (13 per cent) were found to be blind on follow-up study of two years or longer. Although the available data are insufficient to determine whether artificial fever is as effective as malaria therapy, the former is definitely an important addition to the therapeutic armamentarium.

INHIBITION OF CUTANEOUS PAIN RESPONSES BY THE LOCAL APPLICATION OF COLD*

A Simple Method of Reducing the Pain of Hypodermic Injections

FRANC D. INGRAHAM, M.D.,† DONALD D. MATSON, M.D.,‡ AND ROBERT P. WOODS, M.D.‡

BOSTON

THE increased use of antibiotic therapy as well as other medications and fluids administered by hypodermic injection has raised the question of the effectiveness and practicality of employing cold to relieve the pain of the repeated and often terrifying encounters with the needle experienced particularly by sick children. Inquiry revealed that hundreds of intramuscular and subcutaneous injections alone are performed every day at the Children's Hospital. Frequently, the mental and physical anguish associated with the numerous injections given to a critically ill patient is not inconsiderable.

It seemed desirable to determine first of all the physiologic relation between the temperature of the skin and the discharge of impulses from cutaneous pain receptors. That nerve conduction may be temporarily interrupted by temperatures that never reach the freezing point is well known. This has been demonstrated clinically by the effectiveness of refrigeration anesthesia in surgery of the extremities. It has also been measured in experimental animals. Denny-Brown and his co-workers¹ cooled the exposed sciatic nerve of cats with circulating brine. They found that when the temperature of the brine was 2°C or higher and the temperature within the nerve itself 8 to 11.6°C for as long as two hours, there was temporary interruption of function with no evidence of any permanent damage to the nerve. Gasser² studied the effect of temperature changes on nerve conduction in the frog. He found that cooling a nerve caused its action potential to decrease in a characteristic way. On cooling from 30 to 20°C, the action potential fell off slowly. The rate of fall then progressively increased, and somewhere in the neighborhood of 10°C the decline became rapid, with failure to respond altogether around 5°C. If cooling was discontinued at that temperature, the process was still reversible, since complete recovery occurred when the nerve was rewarmed.

Few clinical observations have been made on the effect of cooling on cutaneous sensation, although the numbing effects of cold, particularly that applied to the extremities, is a daily observation during ordinary winter exposure. Gammon and Starr,³ in the course of studies on pain relief by counter-irritation, found that cold was most effective when

applied to the skin at a temperature of 4 to 10°C. They observed cold to be more effective in relieving pain caused by irritant surface ointments than electricity, heat, vibration or air-jet stimulation. They accounted for the principal effect of cold in relieving pain on the basis of a decreased peripheral sensory discharge due to lowering of the temperature of the pain endings.

EXPERIMENTAL OBSERVATIONS

Experiments were undertaken to determine the feasibility of quick-cooling a small area of skin to a degree that would permit painless insertion of a needle. The area of skin that need be cooled for any one injection is small, it need remain cooled to an effective degree only long enough to carry out introduction of the needle—fifteen to thirty seconds. A small portable instrument capable of quickly cooling the skin to a degree sufficient to inhibit the cutaneous pain receptors temporarily but not producing pain in itself or any irreversible alterations in the skin or cutaneous receptors involved seemed desirable. Such an instrument, to be of practical value, demanded simplicity and suitability for use by nurses without danger of local skin damage.

After preliminary experiments with carbon dioxide snow in various types of containers, a much simpler instrument was constructed and has proved satisfactory for certain fundamental observations and for the carrying out of numerous clinical trials. A brass cylinder, 5 cm in diameter and 22.5 cm long, closed at one end, was selected. A smaller brass cylinder, 1 cm in diameter and 1 cm in length, was soldered on to the middle of the closed end of the larger cylinder. This small cylinder was filled with solder (20 per cent lead and 80 per cent tin), a rapid conductor of heat. The large cylinder was wrapped with felt 0.5 cm in thickness. It was filled with cracked ice to which was added anhydrous calcium chloride. The open end of the cylinder was occluded by a tightly fitting rubber cork. The opposite, or contact end, was covered by a hollowed-out, closely fitting rubber cap. This gave a compact insulated instrument with a cooled round metallic contact surface 1 cm in diameter (Fig. 1). It was found that with cracked ice alone in the brass cylinder, the temperature of the contact surface, as determined by an iron-constantan thermocouple (L & N Potentiometer), was about 7.5 to 9.5°C. By the addition of varying amounts of calcium

chloride to the cracked ice the temperature of the contact surface could be reduced as low as -4°C . If the cylinder was kept completely insulated — that is, with the rubber cap over the contact surface except when in use — the temperature of the contact remained at approximately the same level for several hours. If the instrument remained in a refrigerator when not in use, the temperature of the contact could be kept at desired levels for longer periods.

Numerous observations were first made on healthy subjects, to determine the effectiveness of this cooling metallic contact in reducing the skin tem-

thumb and index finger so as to exert counterpressure, there was no sensation when the needle was inserted.

Experiments were performed to determine the optimum temperature of the metal contact. It was found that a contact temperature of 4 to 6°C proved most satisfactory. If the temperature was below 4°C , application of the contact became uncomfortable and, in areas of thin skin, such as the volar aspect of the forearm, definitely painful, owing to a local burning and aching sensation. If the temperature was above 7°C , the skin was not cooled to the critical level found essential for tem-

AMOUNT OF ANHYDROUS CaCl_2 ADDED = 25 GMS

FIGURE 1 *Instrument for the Local Application of Cold*

perature. These were made at room temperatures of 21 to 28°C . Skin temperatures were recorded from a potentiometer with the use of an iron-constantan thermocouple. Tests were made on many skin areas, notably those generally used for hypodermic injections: the lateral aspect of the upper arm, the lateral and dorsal aspects of the thigh, the lateral aspect of the buttock and the volar and dorsal surfaces of the forearm. It was soon determined that when the skin temperature was reduced to a point between 11 and 14°C , preferably below 13°C (normal skin temperature equals 31 to 34°C), an ordinary No. 23 to 19 hypodermic needle could be introduced through the cooled skin without pain. This proved to be consistent in different subjects, at different testing periods and on different areas of skin. Pressure was perceived by the subject as the needle was pushed through the cooled skin, but no pain. If the cooled skin was elevated and pinched between the operator's

porary inhibition of cutaneous pain receptors. The ideal temperature, therefore, was $\pm 5^{\circ}\text{C}$. It was found that 25 gm of anhydrous calcium chloride added to the 400 cc of cracked ice in the instrument used consistently produced this temperature of the metal contact. By determination of skin temperatures in various areas of the body after the contact had been applied at temperatures between 4.4 and 5.5°C for varying periods, it was observed that forty-five to sixty seconds' cooling was adequate to reduce the skin temperature to the critical level for anesthesia (Fig. 2). The temperature remained within this range for thirty to sixty seconds. After that period, sensation gradually returned as the skin became warmer. The application of a tourniquet to the extremity proximal to the point of cooling did not affect the rate or degree of reduction of skin temperature by this method.

Cooling the surface of the skin did not lessen the discomfort of intradermal injections of fluid. After cooling of the skin to 11 to 13°C an intradermal needle could be inserted entirely without pain, but subsequent injection of novocain or physiologic saline solution produced a momentary, intensely painful sensation, presumably by providing a different type of stimulus (distention of the skin),

also be pain on actual injection into the substance of the muscle, depending on the nature and amount of the material injected.

It can also be used satisfactorily in routine venipunctures. The needle is inserted painlessly through a cooled area of skin immediately over or adjacent to a prominent superficial vein. Once through the skin there is little or no pain connected with seeking

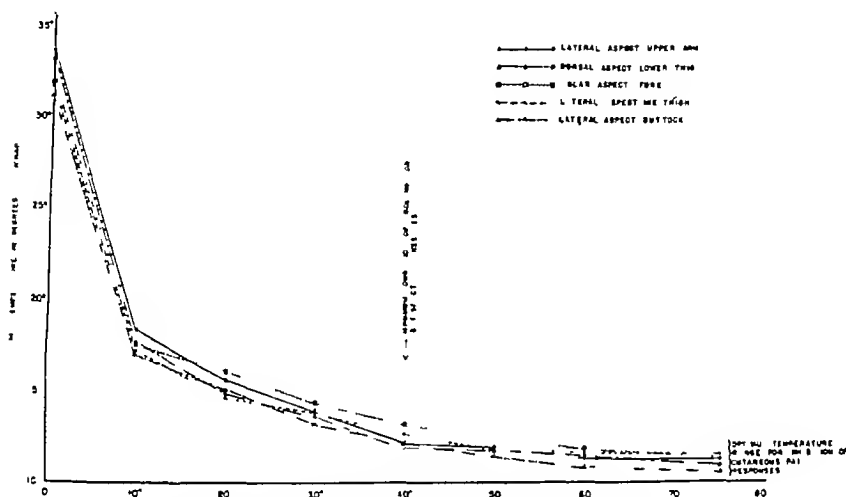

FIGURE 2 Duration of Cooling with Metal Contact at 4.4 to 5.4°C

The time is expressed in seconds and each point charted represents the average of three readings

which stimulated cutaneous endings not affected by the cooling. The method, therefore, is unsatisfactory for preliminary anesthesia of an area of skin subsequently to be anesthetized for prolonged insertion of a needle — as in lumbar puncture.

CLINICAL APPLICATION

The application of this principle of local quick-cooling of the skin is widest naturally for subcutaneous injections; these can be done entirely without pain by the application of a metal contact whose temperature is $\pm 5^\circ\text{C}$ to an area of skin for forty-five to sixty seconds, especially if the pressure of insertion of the needle is eliminated by counter-pressure on the adjacent skin. A metal contact at 5°C feels cold but is not uncomfortable in that length of time except over areas of extremely thin skin. On the lateral aspect of the upper arm, the thigh and the buttock it is not at all unpleasant. The method is extremely effective for intramuscular injections, although occasionally slight twinges of pain are felt as the fascia is pierced, and there may

the lumen of the vein with the point of the needle. If the procedure takes longer than sixty seconds owing to the operator's inability to insert the needle into the vein promptly, manipulations of the needle at the skin surface will again be painful.

This device has been used as follows on numerous children, as well as on adult patients. If old enough, the patient is told about the purpose of the cooling metal disk. Since most patients have had previous painful injections, they are receptive to its use. The skin area to be injected is prepared as usual by being wiped clean with an alcohol or Zephiran sponge. The rubber cap is removed from the cold contact surface, and the latter is also wiped with an alcohol or Zephiran sponge. The contact surface is held against the cleaned skin for forty-five to sixty seconds. The cooled skin is then gently elevated by squeezing together of the adjacent skin on either side, and injection performed through the center of the cooled area within thirty seconds. If patients looked away they were frequently entirely unable to tell the moment of insertion of the needle.

This method of local quick-cooling has been used satisfactorily for all types of subcutaneous medications, intramuscular chemotherapy, venipuncture for removal of blood and administration of drugs and for the insertion of subcutaneous clyses

SUMMARY

When the skin temperature is reduced to 11 to 13°C by external application of cold to a small area, pain responses to cutaneous stimuli in this area are inhibited

A smooth metal disk at a temperature of $\pm 5^\circ\text{C}$ held against the skin for forty-five to sixty seconds will reduce the skin temperature to 11 to 13°C for periods of thirty to sixty seconds

During that interval hypodermic needles can be inserted through the cooled skin entirely without pain, and with no sensation if the pressure of intro-

duction of the needle is equalized by counter-pressure on the adjacent skin

Reducing the skin temperature locally to this level is without danger, produces no irreversible changes and is not uncomfortable

The method has been found useful, particularly in children, for the carrying out of painless hypodermic injections and all forms of parenteral therapy

Any simple device, such as the one described above, that will provide a small metallic surface at a temperature consistently in the neighborhood of 5°C is suitable for practical use in office or hospital

MEDICAL PROGRESS

PRACTICAL CONSIDERATIONS OF VENOUS PRESSURE*

HUGH HUDSON HUSSEY, M D,† AND HAROLD JÈGHERS, M D‡

WASHINGTON, D C

CLINICAL interest in venous pressure has centered mainly on the alteration in its measurement in cases of heart disease¹⁻⁷ In this connection most of the literature on the subject is concerned with the utility of venous-pressure measurement in confirming the diagnosis and following the progress of congestive heart failure In addition, in the past few years the results of studies of venous pressure in its relation to the mechanism of heart failure have provoked a lively debate At the same time there have been noteworthy improvements in technic of measurement, as well as increasing awareness of the value of the test in the diagnosis and study of a number of other conditions, including pericarditis, thoracoplasty, shock and a variety of causes of localized venous obstruction

NORMAL PHYSIOLOGY

Before the clinical application of venous-pressure measurement is reviewed, it seems advisable to recall briefly the normal physiology of venous flow It is obvious at the start that the initial impetus to

flow of blood in the systemic veins is imparted by the propulsive action of the heart and arteries Of course, the capillary bed has a dampening effect on this action, so that the rate and volume of blood flow in the veins are more directly related to capillary pressure and flow It is essential to remember also that the veins adjust their capacity nicely to the volume of blood delivered by the capillaries, this adjustment depending on the same nervous and humoral influences that affect arteriolar and capillary tone At the other end of the venous circulation the heart has an important regulatory effect because of its ability normally to alter its output to suit wide variations in the volume of venous return On this account, stagnation of blood in the veins is prevented under conditions in which venous return is increased The flow of blood through the systemic veins receives another important propulsive force from the tone and intermittent contraction of the skeletal muscles This force moves blood only in the direction of the heart because of the arrangement of the venous valves Another factor that exerts a major influence in favor of venous return is the negative intrathoracic pressure This produces an expansion of the thin-walled intrathoracic veins so that venous blood tends to be sucked into the thorax Since the negative pressure in the thorax increases during inspiration and decreases during expiration, venous pressure fluctuates accordingly during the

phases of respiration. Finally it must be mentioned that gravity influences venous flow and venous pressure. It is generally accepted that the right atrium represents the zero hydrostatic level for the blood in the veins—that is, the level at which gravity has no influence. In a vein located below this level, therefore, part of the venous pressure represents the weight of the column of blood interposed between the vein and the right atrium. It must be kept in mind that the effect of gravity is minimized by several mechanisms, including intramuscular pressure, muscle contraction, intra-abdominal tension and the system of venous valves.

Although there are numerous variables in the physiology of venous flow, some of them counterbalance in such a manner that venous pressure tends to be remarkably constant in normal subjects. In addition, the technic of measurement of venous pressure removes other variables. Before the measurement is made the patient is required to rest in bed for fifteen to thirty minutes. This prevents any alteration that might otherwise result from the effect of exertion.² During the test the patient is supine with the arm at an angle of 45° to the body and in such a position that the antecubital vein to be used is at or just below the level of the right atrium. This position of the arm eliminates any tendency to compression or torsion of the axillary or subclavian vein, which may result when the arm is closer to the side or more fully abducted.² Also, the fact that the vein selected for venipuncture is not above heart level prevents errors in measurement that might otherwise result from collapse of such superficial veins.² An effort is made to have the patient relax fully, so that muscle tension will not alter the results, and he is instructed to breathe easily and regularly to avoid the effects of alteration of the intrathoracic pressure. Apnea, sighing, straining, coughing, talking and other variations in the respiratory act prevent accurate evaluation of the venous pressure.⁴ The supine position minimizes the effect of gravity, and in addition, the hydrostatic factor should be entirely eliminated by the use of a level for reference of the venous-pressure measurement at which hydrostatic pressure is zero.

A number of different zero levels have been used, and this has naturally led to some variation in the values reported for normal venous pressure.^{2,3} Needless confusion has developed concerning the significance of this point. As a matter of fact, the selection of the zero level has made little practical difference in the results reported by various authors, except that the results must be evaluated individually and cannot be used interchangeably. The situation is analogous to that which obtains in connection with a laboratory test like the erythrocyte sedimentation rate. Various technics have been used, and the values found with one technic are not the same as those found with another, although they are individually valid. There is much to recommend the zero level

selected by Lyons, Kennedy and Burwell at a point 10 cm from the skin of the patient's back when the supine position is utilized. This level closely approximates the plane of the right atrium and agrees remarkably well with results obtained by Holt⁶ in a detailed study of the problem of eliminating the hydrostatic factor during venous-pressure measurement. Winsor and Burch⁸ advocate the use of the "phlebostatic axis" to find the zero level for reference. They define the axis as a line resulting from the intersection of a frontal plane passing midway between the posterior surface of the body and the base of the xiphoid process, with a cross-sectional plane passing through the fourth intercostal space adjacent to the sternum. A horizontal plane passing through this axis is the phlebostatic level. The use of this level is recommended by its originators because it is supposed to give the same results regardless of the position of the patient. This appears to be true for normal persons but is far from true for patients with venous hypertension from any cause,^{3,4} so that the arguments in favor of employing this reference level lose their force. With the patient supine the same reference level that is used for measurement of the venous pressure in the arm veins should be used for those in other veins, such as the femoral, for purposes of comparison.

TECHNICS

The numerous variations in technic for measurement of venous blood pressure can be grouped in three categories, as follows: clinical inspection of superficial veins, the indirect method and the direct method.

Clinical Inspection of Superficial Veins

Inspection of suitable superficial veins is useful for estimation of the venous pressure only when the pressure is higher than normal, so that the veins are abnormally distended. Probably the most widely employed technic entails inspection of the external jugular veins.^{10,11} When a patient is in a semi-sitting position, these veins normally are not filled above the plane of the manubrium. Distention of the veins above this level indicates that the venous pressure is abnormally high, at least in the superior-vena-cava system (Fig 1). This finding in a patient who also has hepatomegaly with or without edema of the lower part of the body permits the conclusion that there is a generalized elevation of the venous pressure above normal, such as that in congestive heart failure. At times in heart failure, abnormal distention of the jugular veins is not detected until the abdomen is firmly compressed, or this maneuver may increase the amount of distention (hepatojugular reflux). This point is discussed below in full.

Another technic for determining that the venous pressure is abnormally high was originally described by Gaertner.^{12,14} With the patient sitting and relaxed, the superficial veins of the hand are watched

for collapse while the arm is slowly raised. The distance of the point at which collapse is observed from the plane of the right atrium (taken as the fourth intercostal space) is a rough measurement of the venous pressure. Normally, it is equivalent to 100 mm of water.

In a third technic the veins on the undersurface of the tongue are inspected while the patient is sitting.¹⁵ When the venous pressure is equivalent to more than about 200 mm of water these veins are obviously distended; normally, they are collapsed.

The inspection procedures described above afford a rough qualitative means for evaluation of the venous pressure, mainly in cases of heart failure. When the findings are positive it is fairly safe to conclude that the venous pressure is higher than normal, although rather wide variations of degree cannot be assayed. When the findings are negative

look the fact that distention of the superficial veins more frequently indicates local obstruction of the deep veins than vice versa. An excellent example of this tendency is in cases of varicose veins of the lower extremities, which the physician often treats as a cosmetic problem without troubling to decide whether or not they are a consequence of deep venous occlusion.

Indirect Method

The indirect method of measurement of venous pressure no longer has wide popularity, although it was extensively employed by Eyster¹ and a few other workers.¹⁶ It depends on the principle that the least pressure necessary to cause collapse of a vein is approximately equal to the pressure within its lumen. The main advantage of this method is that since venipuncture is avoided it can be used

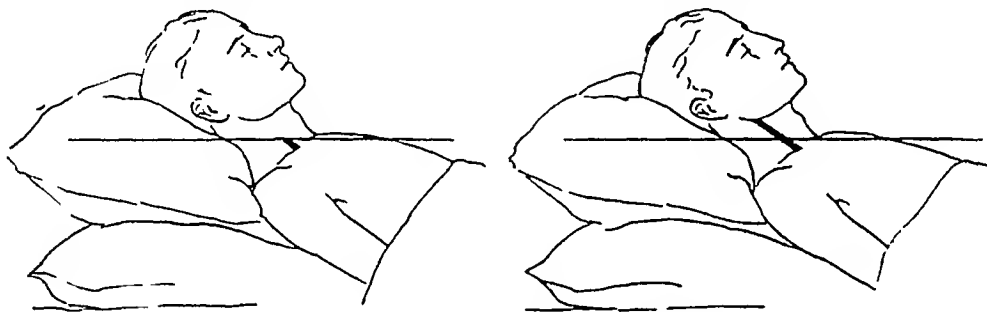

FIGURE 1 Normal and Distended External Jugular Vein

The sketch on the left demonstrates an external jugular vein normally filled, that on the right shows an external jugular vein filled to an abnormal height as a result of increased venous pressure (reproduced from Hussey¹² by permission of the publisher)

it is not safe to conclude that the venous pressure is within normal limits. This is true because a patient with heart failure, for example, may have a high venous pressure while supine and normal venous pressure while sitting.^{3, 4} Elevated pressure of long duration is more likely to show clinically detectable venous distention than when it is of recent onset. Superficial veins in elderly persons are occasionally sclerotic and do not readily distend or collapse with variations in venous pressure.

Inspection of the superficial veins is a much more reliable diagnostic aid for detection of localized venous obstruction. The pattern of the superficial veins in the distribution of the collateral circulation of the obstructed vein contrasts so distinctly with the appearance of the superficial veins elsewhere that suspicion of the diagnosis is obtained with the first glance. Two words of caution may be valuable regarding this point. In the first place, there are considerable differences in the visibility of the superficial veins of different persons, depending on the quality of the skin as well as anatomic variations in the venous pattern. It is important to remember, therefore, that the superficial veins must be distended, not merely visible, before they are accepted as evidence of localized venous obstruction. Secondly, there is probably a great tendency to over-

frequently and painlessly in the same patient. This advantage is outweighed by many disadvantages, including the difficulty of learning to use the apparatus skillfully, the failure of the test when the superficial veins are sclerotic or not visible and the fact that the venous wall may manifest hypertonus in some cases of heart failure.

Direct Method

The direct method is the one most generally employed when results more accurate than those that can be obtained by simple inspection of the veins are desired. It consists essentially of measuring the venous pressure through a needle that has been inserted into the vein. A variety of instruments have been devised for this purpose.^{12, 17-27} Most of them adopt the principle of a liquid manometer so that the measurement is represented directly as millimeters of physiologic saline solution, the liquid usually employed. An apparatus of this type that has given satisfaction during extensive trial is shown in Figure 2. This instrument is sterilized by boiling or autoclaving before it is used. It consists of a glass measuring tube (A) having a 3-mm or 4-mm bore and attached by rubber tubing to a three-way stopcock (C). Affixed to the appropriate adapters of the stopcock are a 5-cc or 10-cc syringe (B) con-

taining sterile saline solution and a 19-gauge or 20-gauge needle 3.7 cm long (D). The rubber tubing and glass are filled from the syringe, and the stopcock is then turned so that solution from the syringe can be injected into the vein to be punctured. If the venous pressure only is to be measured, the syringe is left partly filled with saline solution. If the circulation time is to be measured as part of the procedure, the syringe is filled with the agent used for this purpose. After venipuncture the stopcock is turned to the position that permits the solution to enter the vein from the measuring tube. Details regarding the position of the patient and

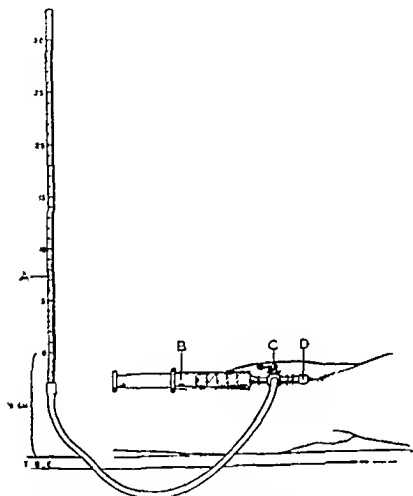

FIGURE 2. Apparatus for Measurements of Venous Pressure (Reproduced from Hussey¹³ by Permission of the Publisher)

other essentials of technic during the procedure have been discussed above. For the moment, it is sufficient to say that the column of liquid in the measuring tube fluctuates lazily with respiration and sometimes sharply with the arterial pulse. The introduction of a needle into the vein may produce a temporary venospasm, which tends to raise the venous pressure. Ordinarily, the effect disappears within so short a time as to be a negligible factor. The tendency of the initial high value to drop to a constant level has been called "venous pressure drift."

The apparatus described, although entirely suitable in hospital practice, is not completely satisfactory for routine use as a part of the examination equipment of the average physician. With this consideration in mind Burch and Winsor¹ have devised the "phlebomanometer." This instrument adapts

the principles of the aneroid manometer used clinically for recording arterial blood pressure to a manometer sensitive enough to register venous pressure. It is compact and portable and appears simple enough to be popular.

The instruments for direct measurement of venous pressure can be used in any accessible vein. The discussion presented below indicates that in some cases it is desirable to compare measurements in several different veins in the same patient. In the lower extremity the best vein for such comparisons is the femoral.^{24, 25} This vein is punctured according to the technic of Griffith, Chamberlain and Kitchell¹³ by insertion of a needle upward and inward at a point 2.5 cm distal to the inguinal ligament and just medial to the pulsation of the femoral artery. No tourniquet is required. The angle that the needle makes with the skin of the thigh and the depth to which it is introduced must be varied with the thickness of the tissues overlying the femoral vessels. For almost all cases a needle 3.7 cm long is adequate.

Other veins in the lower extremity than the femoral may be utilized for venous-pressure determinations. A number of French clinicians favor the use of the greater saphenous near the femoral triangle in place of the femoral vein.²⁶⁻²⁹ If the greater saphenous vein at a lower level or the dorsal pedal vein is used, due consideration must be given to the gradient of pressures the more distal the vein is located from the heart.³ For example, in a typical case the pressure of the dorsal pedal vein was 40 mm more than that in the greater saphenous vein at a higher level.³ The problem of gradient of pressures has been well discussed by Winsor and Burch¹ and Burton-Opitz.³¹ This pressure gradient also holds for the upper extremity. For example, the dorsal-metacarpal-vein pressure may be about 10 mm higher than that in the median basilic and 50 mm higher than that in the cephalic or jugular vein.³ Measurements of the pressure in the popliteal veins have also been made in a study of the effects of localized obstruction to venous flow in the lower extremities.³² For this purpose the patient is standing and the "local" venous pressure only is measured by means of a mercury manometer. The difficulties of technic will prevent this method from being used except for research. Venous pressure may also be determined in the internal or external jugular vein.^{33, 34}

NORMAL VALUES

Normal values for venous pressure measured by the direct method have varied in the experience of different authors on account of technical differences in their studies. The principal reason, as mentioned above, has been the lack of uniformity for selection of the zero level for reference of the measurement. When the zero level is placed at a point 10 cm from the skin of the patient's back the venous pressure

in the arms is normally equivalent to 50 to 150 mm of saline solution ² The values reported by Winsor and Burch³ using a slightly different zero level were essentially the same Normally, the pressure in the femoral vein is usually about equal to or a little higher than that in the antecubital vein of the same person ^{5, 24, 25} In some subjects, particularly those who are obese, the femoral-vein pressure may be as much as 40 mm of saline solution higher than the antecubital pressure

According to Jacques²⁶ there appears to be little difference between venous pressures in adults and children when they are considered collectively and studied under the same conditions of technic Eighty-three per cent of measurements were equivalent

out evidence of heart failure Szekely³⁵ noted that some showed a pathologic response Presumably, these were cases of latent cardiac failure These studies in human beings are interesting in view of the demonstration by Landis³⁶ that experimental damage to the heart of the dog did not produce a rise in venous pressure until the effect of exercise was superimposed On the basis of his experiments Landis commented that this could explain the development of right-upper-quadrant pain and a palpable liver after exercise in a cardiac patient whose resting venous pressure is normal

When venous outflow from an extremity is obstructed locally, exercise of the extremity causes a progressive increase in venous pressure above the

TABLE 1 *Diagnostic Value of Regional Differences in Venous Pressures*

PRESSURE DATA	DIAGNOSIS
Diminished in all peripheral veins	Peripheral vascular collapse (shock), syncope.
Elevated in all peripheral veins	Right-sided and generalized cardiac failure, constrictive pericarditis (Pick disease), pericardial effusion, uniform loss of negative chest pressure (obstructive emphysema), Bernheim syndrome, varicose veins
Normal arm and elevated in leg veins*	Ascites, tympanites, pneumoperitoneum, pregnancy, hypernephroma and other tumors of kidney, with invasion of inferior vena cava, primary carcinoma of liver, with invasion of inferior vena cava, primary tumor of inferior vena cava, thrombosis of inferior vena cava, ligation of inferior vena cava masses in peritoneal cavity, solitary abscess in right lobe of liver, subphrenic abscess on right, echinococcus cyst of liver large tumor mass in right lobe of liver
Elevated in arm and normal in leg veins	Aneurysm of aorta, dilatation of aorta, lymphoma of mediastinum, metastatic masses in mediastinum primary tumor of mediastinal structures, abscess of mediastinum, thrombosis of superior vena cava
More elevated in one arm than in other and lower or normal in leg veins	Localized obstruction of axillary or subclavian veins due to exertion, pressure from neoplasm, cardiac failure, unilateral chest lesions (pleural effusion, pneumothorax, thoracoplasty), aneurysm of aorta (85% higher on left than on right), aneurysm of innominate artery (higher on right than on left), arteriovenous fistula of arm
More elevated in one leg than in other and lower or normal in arm veins	Arteriovenous fistula of leg, thrombosis of femoral or iliac vein
Dissociation between internal jugular vein and general peripheral venous system	Polycythemia or mass in neck or upper mediastinum (elevated pressure) thrombosis of lateral sinus (diminished pressure)
Elevated in portal vein and normal in arm and leg veins	Cirrhosis of liver obstruction of portal vein, obstruction of splenic vein, Chlari syndrome.

*Also observed during abdominal operations

lent to between 80 and 130 mm of water Lambert²⁷ has also reported on venous-pressure values in normal children

RESPONSE TO EXERCISE

Venous-pressure response to exercise, under certain conditions, affords a means of enhancing the value of the determinations A reasonably extensive literature exists on this subject This has been reviewed by Szekely³⁵ A standardized technic for measuring venous pressure during and after exercise has been devised and gives reasonably consistent results³⁵ In normal subjects the venous pressure rises from 20 to 50 mm of water during exercise and returns to or slightly below the basal level within thirty seconds after cessation of the exercise³⁵ In patients with heart failure it rises much higher with exercise and returns to the initial level more slowly³⁵ This may be true even though the resting venous pressure of such a cardiac patient is normal In a group of patients with cardiac disease and with-

resting level, and return to this level is slow ^{32, 37} This technic can be readily employed when the upper extremity is involved ^{32, 37}

The exercise of the upper extremity consists of repeated clenching of the fist for one minute Normally, the venous pressure falls slightly or remains stationary except for minor fluctuations during the exercise Local obstruction anywhere from the axillary vein to the superior vena cava produces a steady increase in venous pressure during the one minute of the exercise test The magnitude of the rise varies from 10 to 900 mm of water ^{32, 37} This hand-clenching exercise is without effect in cardiac patients presumably because it is not strenuous enough to cause a general effect Similar results are obtained when the popliteal vein is used to test for obstruction of veins of the lower extremity or pelvis ^{32, 37} In constrictive pericarditis, the effect of local exercise (clenching fists) may be the same as in cases of local venous obstruction of the upper extremity in con-

trast to what is obtained in cardiac failure.²²⁻²⁴ This has been noted in 3 typical cases.²²⁻²⁴

HEPATOJUGULAR REFLUX

It was mentioned above that distention of the cervical veins in heart failure may become apparent for the first time when the patient's abdomen is firmly compressed. This phenomenon was originally described by Pasteur²⁵ and later by Rondot.²⁶ It has since been called the hepatojugular reflux and also the Pasteur-Rondot phenomenon. The use of this maneuver has been commented on by Fishberg²⁷ and extensively studied by Oppenheimer and Hitzig²⁸ and by Hitzig.²⁹⁻³¹ It depends on the fact that abdominal compression quickly increases the return of blood through the inferior vena cava from the congested viscera, especially the liver, so that, in a sense, there is competition of this augmented flow with blood arriving from the superior vena cava. Because the heart is failing, the increased venous return is not accommodated, and consequent stagnation of blood in the superior vena cava is reflected as an increase in venous pressure in the tributaries of this vessel.³² The same effect may be expected when there is a general increase in venous pressure from some other cause, such as constrictive pericarditis or pericardial effusion. When the superior vena cava is extensively obstructed the same phenomenon is observed, although the mechanism is different.³³⁻³⁵ Here the effect of compression of the abdomen is to impede flow of blood through the inferior vena cava. Since in this syndrome this is the main route for ingress of blood from the superior-vena-cava system as well, pressure rises in the veins of this system. A similar result is obtained when the large superficial collateral veins of the trunk are occluded by means of a band encircling the thorax.³⁶

For obvious technical reasons the influence of abdominal compression on venous pressure can best be evaluated by direct measurement. When an initial reading of the venous-pressure measurement has been obtained by the technique described above, the examiner compresses the patient's abdomen, preferably the right upper quadrant, for one minute. Care is taken to apply the compression gradually so that there will be no interference with the rate, rhythm or depth of respiration and no tendency for the patient to tense his muscles. Normally, with the maneuver, the pressure in the antecubital vein remains unchanged or falls.³⁷⁻⁴⁰ This effect is explained by the fact that curtailment of venous return from the inferior vena cava encourages a more rapid emptying of the superior-vena-cava system. In conditions causing general elevation of the venous pressure above normal and in the superior-vena-cava syndrome, the maneuver causes a rise of 10 mm or more of water in the arm vein pressure. It is of considerable diagnostic importance that in cases of mild or latent heart failure the same effect is obtained,

although the venous pressure initially may be within normal limits.³⁷⁻⁴⁰ It has also been demonstrated that the venous pressure in the arms rises 30 mm or more in patients with heart failure when the legs are raised from the bed while the trunk remains horizontal (Azoulay position).⁴¹⁻⁴³ This finding has a significance equivalent to the hepatojugular reflux.

RELATION OF SPINAL-FLUID TO SYSTEMIC VENOUS PRESSURE

It is well established scientifically that a close relation exists between spinal-fluid pressure and cerebral venous pressure.⁴⁴ Except under certain rare conditions in which there is a dissociation between the internal jugular-vein and arm-vein pressures, which is discussed in greater detail below, the cerebral venous pressure reflects the general systemic venous pressure⁴⁵⁻⁴⁷ or occasionally the pressure existing in the superior-vena-cava system.⁴⁸ A number of practical points about this relation are frequently overlooked in clinical practice.

The spinal-fluid pressure is increased in any of the conditions listed under the heading "elevated venous pressure in all peripheral veins" in Table 1 and in any other disease referred to in the table that involves the venous return through the superior vena cava. Harrison⁴⁹ found in normal people, as well as in patients with cardiac failure and elevated venous pressure, a definite ratio of spinal-fluid pressure to venous pressure that averaged 1.6. Therefore, if a spinal-fluid pressure is found to be elevated and no central-nervous-system disease appears to be the cause, a check on the arm-vein pressure is indicated. Increased spinal-fluid pressure secondary to high venous pressure has been suggested as the cause of a number of central-nervous-system manifestations.

(To be concluded)

CASE 33471

PRESENTATION OF CASE

A sixty-four-year-old man entered the hospital because of pain in the left flank

Eighteen years before admission the patient was told that he had bilateral kidney stones. Since that time frequent x-ray studies had been made, and the stones did not appear larger. He felt reasonably well until a year before entry, when he began to have malaise, anorexia, pallor and twinges of pain in the left flank. This pain became more frequent and severe, and for the previous month had been constant. It radiated from the flank to the lower back and groin and down the anterolateral aspect of the left thigh. There was nocturia (two or three times) and questionable hematuria.

The past history was irrelevant except for meningitis at the age of sixteen years, which had left the patient partially deaf in the right ear.

Physical examination revealed a thin, sallow man with a large, firm, tender, fixed mass in the region of the left kidney and a soft, apical systolic murmur. Neurologic examination disclosed bilateral Babinski reflexes, bilateral clonus, hyperactive reflexes, absent vibration sense at the right ankle, facial palsy on the right and Hoffmann's sign on the right.

The temperature was 100°F, the pulse 100, and the respirations 20. The blood pressure was 125 systolic, 70 diastolic.

Examination of the blood revealed a white-cell count of 15,600 and a hemoglobin of 7.5 gm. The urine gave a + test for albumin, the sediment contained only an occasional red and white cell per high-power field. The nonprotein nitrogen was 41 mg and the total protein 6.4 gm per 100 cc, and the alkaline phosphatase 5.7 Bodansky units. The carbon dioxide, chloride, calcium and phosphorus were within normal limits.

A plain x-ray film showed bilateral, irregular, stag-horn calculi (Fig 1). On the left side there was also irregular calcification overlying the lower pole of the kidney. There were several smaller areas of calcification in the right paravertebral region and pelvis, one of which was in line with the ureter.

A cystoscopy with ureteral catheterization and retrograde pyelography was done. The bladder

showed numerous calculi lying over the floor and a rather marked trabeculation. At the vesical orifice there was some enlargement of the median portion of the prostate. The left ureteral orifice was catheterized without great difficulty, but after the catheter had ascended to the upper ureter, it could not be pushed through into the renal pelvis and no drainage of urine occurred and none could be

The patient was given a total of 2500 cc of whole blood, which finally raised the hemoglobin to 114 gm. An operation was done on the tenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. F. A. SIMEONE This is the story of a sixty-four-year-old man who had calculi in both kidneys for ten years, but who had no symptoms from them, from an associated lesion or from an entirely new lesion until one year before entry. During this year he began to have malaise, anorexia, pallor and twinges of pain in the left flank. Taking for granted that he had stag-horn calculi and a few smaller calculi in the renal pelvis, these attacks might represent the repeated passage of small stones, perhaps culminating in increasing infection and possibly total obstruction of the kidney. The pain radiated from the flank to the lower back and

FIGURE 1 Plain Film of the Abdomen

aspirated. On the right side a catheter passed easily to the kidney, and the passage of the catheter was followed by rather clear urine.

Retrograde pyelography on the right side showed opaque material in the lower group of dilated calyces surrounding the calcification here as well as that in the kidney pelvis (Fig 2). None of the material was seen to enter the upper group except possibly in one infundibulum. The group of calcifications in the midabdomen was outside the ureter. A small bit of calcification in the right pelvis was probably within the distal ureter, which was slightly widened. On the left side the opaque medium also projected into the lower group of calyces and extended into the calcification in the lower pole. Medial to the left renal pelvis the dye was seen as mottled, irregular areas of increased density. None was seen in the ureter.

Cultures of urine from the bladder and right kidney were negative.

FIGURE 2 Retrograde Pyelogram of Left Kidney

groin and to the anterolateral aspect of the left thigh. In the presence of a fixed palpable tumor in the left flank, this distribution of pain does not help further in the diagnosis but suggests that the mass was impinging on the lumbosacral plexus thereby explaining the radiation of the pain into the thigh.

The past history was irrelevant.

In the physical examination the important point was the large, firm, tender, fixed mass in the left kidney region. I do not believe that the soft apical systolic murmur was of significance, particularly in the presence of anemia. Many neurologic signs were described, but I am unable to connect them with the lesion in the flank. If it was a tumor, I do not believe that we can assume that there were metastases to the brain on the basis of the findings given. What seems more probable is that the signs represented pyramidal-tract disease as a result of the arteriosclerosis.

The slightly elevated temperature and pulse rate are consistent with an inflammatory lesion in the region of the left kidney, although a malignant lesion is not ruled out, because even in the absence of demonstrated necrosis in the tumor, renal tumors or other large tumors in that region might be accompanied by febrile reactions. Examination of the blood showed a leukocytosis, which is again consistent with an inflammatory lesion, but does not rule out the possibility of a malignant lesion. The hemoglobin of 7.5 gm per 100 cc, or approximately 50 per cent of what it should be, might be attributed to the urinary-tract infection for a matter of years, which we know this man had, and perhaps to the occasional bleeding into the urine as suggested by the questionable hematuria. There was a slight amount of albumin and only an occasional red and white cell per high-power field. The interesting point about that finding is that the urine did not disclose more abnormalities. The nonprotein nitrogen of 41 mg per 100 cc suggests some decrease in the function of the kidneys. The alkaline phosphatase was perhaps within the upper limits of normal. I do not believe that it suggests bone metastases. The calcium and phosphorus concentrations in the serum were within normal limits, which should rule out hyperparathyroidism.

We finally come to the x-ray examination, which yields more definite information. In the first place there were stag-horn calculi bilaterally, and on the left side irregular calcification overlying the lower pole of the kidney. There were several smaller areas of calcification in the right paravertebral region, one of which was in line with the ureter. As described, this makes one wonder whether the lesion was tuberculosis. There is nothing to suggest psoas abscesses with calcification in them. No mention is made of bone disease on x-ray examination, which one would expect under such circumstances. Since an intravenous pyelogram is not recorded I shall assume that it was not done, perhaps because the renal function was not considered adequate to yield a satisfactory pyelogram.

A cystoscopy was done and it gave some specific information. Irregular calculi were found in the floor of the bladder and these perhaps came down from the calyces of the kidney and may have come from the lesion, thereby accounting for the

twinges of left-flank pain that the patient had had during the preceding year. The enlargement of the median portion of the prostate is not particularly remarkable except that it helps to explain why these calculi were not passed from within the bladder.

We have the statement that the left ureteral orifice was catheterized without difficulty, but after the catheter had ascended to the upper ureter it could not be pushed through into the renal pelvis. No drainage of urine occurred, and none could be aspirated. That suggests an obstruction, perhaps in the upper ureter or at the ureteropelvic junction. Furthermore, however, on injection of a contrast medium some of the material did get into the pelvis, into the lower calyces and actually into the region that contained the calcification. It is rather difficult to understand this obstruction to the passage of a catheter into the kidney when no great obstruction was demonstrable to the retrograde injection of dye, and particularly since there was no mention that dye was seen in the left ureter. With a degree of obstruction great enough to prevent the passage of a catheter but not of injected fluid, one would expect some of the solution to reflux down the ureter.

Perhaps we should see the x-ray films now.

DR STANLEY M. WYMAN: The first few films are without dye. An additional point to be mentioned is the possibility of calcification in the left kidney. The calcification lies far lateral in relation to the lumbar spine. There is a suggestion of a mass overlying this portion of the abdomen contiguous with the kidney and perhaps displacing the calcification laterally. This is the calcification described overlying the lower pole. The next film shows the catheter right in the kidney pelvis. Again, the direction taken by the catheter suggests that the kidney is displaced. On the third film we see dye entering the right kidney and lying around the stone and outlining a normal ureter. The last film shows dye in the left kidney around the numerous small areas of calcification in the lower pole and also surrounding, to a slight extent, the large stag-horn calculus. The interesting part is this irregular distribution of dye. It represents perhaps the kidney pelvis and the area just above and medial to it. It is a lacy, irregular pattern of dye that suggests an irregular cavity of some sort, communicating with the kidney pelvis.

DR SIMEONE: Do you think that this dye could be extravasated outside the urinary passage?

DR WYMAN: I cannot say that it is not extravasated and lying free in the peritoneal cavity, but it seems unlikely. I should like to explain the displacement of the stone on some basis connected with this irregular accumulation of dye.

DR SIMEONE: We now come to a differential diagnosis. This man had a tender fixed mass in the left flank. One wonders about lesions in the organs immediately adjacent to the kidney, such

as the descending colon, the spleen and the pancreas, but I think that we can pass these up because we have no data suggesting that these organs have been involved. We might concentrate on a differential diagnosis of the possible lesion that could cause this picture arising from the kidney itself. Before I saw the x-ray films I thought of a number of possibilities, but the films themselves exclude many of them, such as a large parapelvic cyst, which might have calcification in its walls and

Another excellent possibility in this case is perinephric abscess. It would fit in with a certain group of cases associated with renal calculi of long standing. I do not believe that the history of several months' duration is against the diagnosis of the chronic type of perinephric abscess. Renal stones occasionally erode through the pelvis and actually through the renal parenchyma to cause such abscesses. In my mind, the possibilities lie between a carcinoma of the renal pelvis and a

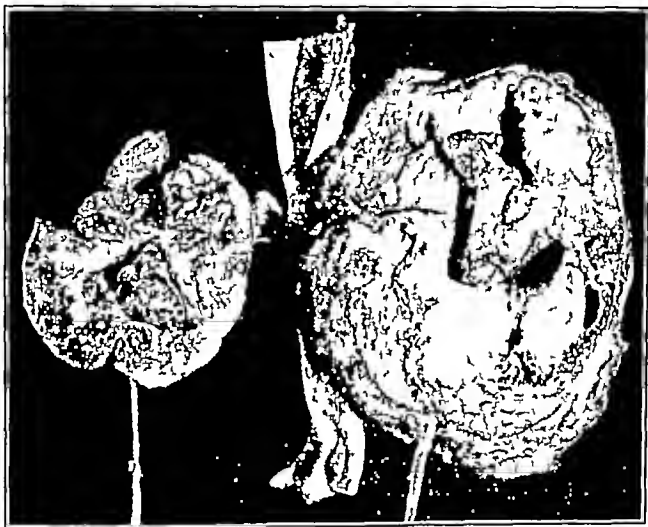

FIGURE 3

might connect with the renal pelvis. The question of tuberculosis also comes up. Tuberculosis does occur in association with stones in a fair proportion of cases at the age of this patient. It would be unusual that nothing was found in the bladder to suggest tuberculosis.

We come next to the question of tumor within the kidney comprising the major bulk of the mass and causing nonfunction of that kidney. Tumors of the renal pelvis, particularly of the nonpapillary type, do occur in association with stones within the renal pelvis and probably more commonly than in kidneys without stones. This is comparable to the greater incidence of carcinoma of the gall bladder in association with gallstones than in the absence of stones. Tumor of the renal pelvis causing nearly complete obstruction at the ureteropelvic junction is therefore a good possibility, and it might explain the failure to get urine from the catheter, since the kidney may have been nonfunctioning.

perinephric abscess. I favor the former diagnosis, a nonpapillary, squamous-cell carcinoma of the renal pelvis, associated with stones.

DR BENJAMIN CASTLEMAN: What did you think about this, Dr Colby?

DR FLETCHER H COLBY: That is exactly the diagnosis that I should have made.

CLINICAL DIAGNOSES

Carcinoma of left kidney, perinephric abscess?
Nephrolithiasis

DR SIMEONE'S DIAGNOSES

Squamous cell carcinoma of left renal pelvis
Nephrolithiasis

ANATOMICAL DIAGNOSES

Squamous cell carcinoma of left kidney, with extension into psoas muscle and with metastases to lung and liver

Nephrolithiasis, bilateral
Duodenal ulcers, multiple (four)

PATHOLOGICAL DISCUSSION

DR CASTLEMAN Dr Leadbetter, will you describe the operative findings?

DR W F LEADBETTER, JR I operated with the expectation of finding either abscess or a degenerative tumor. It turned out to be the latter. It was a large mass that had extended behind and above the kidney, with involvement of the psoas muscle, and well into the connective tissue around the aorta. It was obviously a malignant tumor. I drained it, and there was a good deal of relief for some weeks.

DR CASTLEMAN Autopsy showed a large tumor of the left kidney, which weighed about 1200 gm. The tumor, as Dr Leadbetter has said, extended down into the psoas muscle and formed a fistula with the operative wound. The renal artery opened directly into the mass and was lost in it. The ureter was also imbedded in the mass and the proximal portion of the renal vein was filled with tumor. There was a stag-horn calculus, imbedded in a granular infiltrating tumor that originated in the pelvis (Fig 3). Microscopically, it was a squamous-cell carcinoma. The other kidney also contained calculi, and these were floating in foul green pus. There was one small metastasis to the right lung and a few small ones to the liver.

An incidental finding—and it is amazing that the patient had no symptoms from it—was the presence of four large duodenal ulcers, two in the first portion of the duodenum and two in the second portion, one of which extended to the ampulla of Vater. One had eroded into the pancreas, and another, the most proximal, formed a fistula with the neck of the gall bladder.

DR ISAAC TAYLOR Were the ulcers old?

DR CASTLEMAN No, fairly recent.

CASE 33472

PRESENTATION OF CASE

First admission A seventy-six-year-old man entered the hospital complaining of intermittent periumbilical and left abdominal nonradiating pain of two months' duration.

The patient stated that the pain was dull "like a toothache" and located along a transverse area at the level of the umbilicus, primarily on the left side. There was no known predisposing factor, and there was no change in bowel habits, or melena. Vomiting occasionally resulted in relief of pain. At a community hospital the patient was told that he had jaundice although he had no itching or dark urine. X-ray studies at the hospital were said to have shown a possible neoplasm of the pancreas. During the preceding three months he had felt weak and tired and had an "all-gone" feeling.

Physical examination showed a well nourished man with a Grade II apical systolic murmur. A left direct inguinal hernia was present, abdominal examination was otherwise negative.

The temperature, pulse and respirations were normal. The blood pressure was 130 systolic, 90 diastolic.

Examination of the blood disclosed a hemoglobin of 14.5 gm and a white-cell count of 10,000. The urine showed a 0 to + test for albumin, with a specific gravity of 1.020, and 6 to 20 white cells per high-power field in the sediment. The nonprotein nitrogen was 26 mg per 100 cc, the protein 7.4 gm, and the chloride 100 milliequiv per liter. The prothrombin time was normal. A barium enema showed a few diverticula of the sigmoid but was otherwise not remarkable. An intravenous pyelogram and chest film revealed no significant abnormalities. A gastrointestinal series disclosed prominent lesser-curvature folds in the prepyloric area. The duodenum was deformed, and barium entered the biliary tree.

A sigmoidoscopy was negative. The hernia, which was indirect and contained adherent sigmoid posteriorly, was repaired. The patient did well postoperatively and was discharged four days later.

Second admission (six weeks later) The patient was readmitted because the midabdominal left-lower-quadrant pain had persisted, occurring several times a week, and had been accompanied by vomiting. Twice he had been jaundiced for about a week and had pale stools. Weakness, fatigue and anorexia had appeared. At times a brief "pressing, clamped feeling" had been noted across the epigastrium.

Physical examination was essentially as before. The herniorrhaphy incision was well healed.

A second gastrointestinal series showed the same findings in addition to a duodenal diverticulum. A cholecystogram revealed no filling of the gall bladder. Gastric aspiration demonstrated a + guaiac reaction and no free acid. The white-cell count was 13,600. The urine was normal, except for 30 to 40 white cells per high-power field in the sediment.

The blood chemical findings were normal, including a van den Bergh reaction. A serum amylase test was 7 units per 100 cc.

On the eleventh hospital day a cholecystectomy and choledochostomy were performed. The gall bladder was a mass of scar tissue, with the duodenum drawn up in the scar. The common duct was markedly dilated and contained stones and muddy material. No definite fistula was demonstrated. Postoperatively the systolic blood pressure was between 70 and 80 for seven hours. Two blood transfusions were given, with a gradual rise in blood pressure. Mild congestive failure was treated with digitalization. Prophylactic femoral-vein ligations were performed. On the fourteenth postoperative day the patient was discharged after a cholangiogram showed patent ducts.

Final admission (nineteen days later) Several days after discharge the patient began to vomit three or four times a day. Bile-stained material drained from the operative wound, but the stools remained brown and he was readmitted for study.

Physical examination showed a frail, dehydrated, uncomfortable man with a normal temperature. The lungs were clear and the diaphragm moved equally on both sides. The transverse right upper abdominal incision was indurated laterally, and pus and bile exuded from a sinus.

The white-cell count was 12,800. The urine was essentially normal. The nonprotein nitrogen was 41 mg and the protein 5.5 gm per 100 cc, and the chloride 80 milliequiv per liter. The prothrombin time was 22 seconds, with a control of 17 seconds. A van den Bergh reaction was normal, and the serum amylase was 48 units per 100 cc. Injection of the sinus tract showed a dilated obstructed common duct. A gastrointestinal series revealed thick antral folds but no duodenal defects.

A transduodenal choledochostomy about two weeks after admission disclosed no obstruction, but a pericholedochous abscess was encountered. A duodenal choledochal fistula was present. Postoperatively, the patient did well for a few days but then gradually went downhill. He vomited frequently, the vomitus being guaiac positive. X-ray films showed a narrow nonobstructed duodenum. The pylorus and duodenal loop could not be visualized. While barium was still in the duodenal loop Hippuran injection through the "T" tube revealed a considerably distended common duct, with some pooling near it. There was no certainty that the Hippuran passed through the duodenal loop and small intestine. The main radicle leading to the left lobe of the liver showed a constant, round, filling defect consistent with a retained common-duct stone. The nonprotein nitrogen rose to 96 mg per 100 cc, and the urine output fell. The white-cell count rose to 30,000. On the fourteenth postoperative day the patient fell out of bed and went into shock. He was treated with two transfusions, after which he rallied but gradually lost ground again, developing an irregular pulse and coma. He died four days later.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS D. MOORE. This patient had had so much surgery and so many events on various admissions that the *modus operandi* today will be to follow the same order as that in which he was presented to his physician.

In the first place, he looked well enough at one point so that someone wanted to repair the hernia. He could not have appeared seriously ill. I wonder how much of the story was extracted in retrospect.

He had pain "like a toothache," which has a little significance, meaning probably that it was not a smooth-muscle pain or pain resulting from colic, but was more

likely pain due to a space-occupying process, which could be either a neoplasm or sepsis. This was located in an area to the left of the umbilicus, which certainly suggests the pancreas. Furthermore, he had been told at another hospital that he had jaundice, although he had no itching or dark urine, and I am inclined to believe that the scleras were examined and that slight jaundice was noticed. X-ray studies at that hospital apparently showed something in the region of the pancreas. The patient had an "all-gone" feeling. In other words, he was beginning to have a systemic response to the process, whatever it was.

Then the left inguinal hernia was repaired. At these meetings it is easy to be too critical of what others have done. There is nearly always a good reason, although it may not be apparent. However, we should learn from the warning given in this case that hernias are sometimes misleading. Many patients with a hernia in the inguinal region that has been present for years suddenly experience trouble and come to the doctor. The reason is usually not found in the hernia. There is some other intra-abdominal process causing increased pressure or irritating the peritoneum, which makes the patient notice the hernia. In older people a complete study, prior to herniorrhaphy, is certainly justified. I imagine that the various x-ray films were taken, because the physicians were disturbed about repairing a hernia in this elderly man who had other evidences of disease. It was noted that barium entered the biliary tree—a finding that to my knowledge always coexists with structural disease in that area, I am interested in seeing the film.

DR. TOUFIC KALIL. It was probably a fluoroscopic finding. I do not see it recorded.

DR. MOORE. If the fluoroscopist saw barium entering the biliary tree, that is significant, even if the films are not spectacular. The most frequent cause of air entering the biliary tree is a cholecystoduodenal fistula, which results from a gallstone eroding through into the duodenum. It can also erode through the common duct, and a cholecystocolic fistula can form in the same way and produce the same picture. I have not happened to see other nonsurgical conditions cause it. Of course, surgical maneuvers can produce that picture. The duodenal diverticulum that was demonstrated is not the primary lesion, and its significance as a cause of symptoms or of difficulty of any sort is usually regarded as slight. In any event, in the face of gross roentgenologic evidence of disease around the lower end of the biliary tree, this patient had his hernia repaired and was discharged four days later, which seems to me too early for discharge. Is that correct?

DR. JOHN W. RAKER. That is correct.

DR. MOORE. The patient had a history that was consistent with pancreatic complications. He had x-ray evidence of gross organic disease, with de-

struction of the normal anatomy. At the second admission this process was continuing its inexorable advance, he had been jaundiced, had pale stools and was having intermittent common-duct obstruction. Other symptoms of a systemic nature were present.

The second gastrointestinal series again showed the diverticulum. There was no filling of the gall bladder with a cholecystogram. Without further information it is hard to know whether that is significant, it probably indicates chronic inflammation of the gall bladder. The white-cell count was elevated, indicating a septic process, the urinary sediment showed white cells. The blood chemical levels were generally normal, and included a serum amylase of 7 units per 100 cc. To my way of thinking, that is an unusually low serum amylase, and possibly indicates that the acinar cells of the pancreas were not functioning normally. One sees that occasionally in late chronic pancreatitis, or in neoplasms of the head of the pancreas with chronically obstructed ducts. The serum amylase later went back up to 48 units per 100 cc, and I do not know how to interpret that, possibly extra-pancreatic sources of serum amylase were responsible.

On the eleventh day an operation was performed. Before going on, let us see again if we get any help from x-ray studies done on the second admission.

DR KALIL: These films demonstrate the Hippuran injections through the postoperative tube.

DR MOORE: I do not know what the preoperative diagnosis was. But I think in terms of smoldering chronic pancreatitis superimposed on cholelithiasis and cholecystitis — a combination not too unusual. What was found was a gall bladder showing evidences of cholelithiasis. The duodenum was drawn up to the scarred common duct, which was dilated and contained stones and muddy material. In other words, the caliber of the cystic duct was such as to allow gallstones to pass into the common duct, producing obstruction enough to cause secondary pancreatitis. There was no fistula demonstrated, which is not surprising, it is often difficult to find. I should like to ask Dr Mallory if any note was made at any time regarding the appearance and feel of the pancreas.

DR TRACY B MALLORY: No, there were too many adhesions in the area.

DR MOORE: Femoral-vein ligation was done to keep the patient from dying of pulmonary embolism. A cholangiogram was carried out, and the patient was discharged. Let us see the films of the cholangiogram.

DR KALIL: This is the patent common duct, with the T tube in it.

DR MOORE: The third admission occurred very soon, only nineteen days later. The patient had lost a good deal of ground systemically, and much bile had seeped through the wound. There is no mention that the tube was still in place.

The normal temperature is interesting. It possibly had something to do with the patient's age, because there was an elevated white-cell count and considerable sepsis was found a few days later. He had dehydration, as evidenced by the chemical determinations — a low chloride and a protein of 5.5 gm per 100 cc. It is fair to assume that he had been rehydrated and that the protein went down as a result. The van den Bergh reaction was normal, which is puzzling, but we shall see in a moment a possible explanation for that. The serum amylase was 48 units per 100 cc — back to the normal range.

Injections of the sinus tract showed a dilated, obstructed common duct. I think that this was the film showing the obstruction on the distal end.

DR KALIL: It is a very abrupt ending of the opaque column, rather smoothly rounded, and the material filters down on both sides.

DR MOORE: The common duct is 2 cm in diameter. There is something in the lower end, which could be a stone, but if it is a stone, it is a tremendous one. It could well be a tumor mass.

A transduodenal choledochostomy was done, presumably because of the lesion in the lower end, but nothing was found. That was a surprise. A percholedochous abscess was encountered. There was still sepsis, and the duodenocholedochal fistula was present. The original fistula was finally located and was not cholecystoduodenal but choledochoduodenal. This accounted for the barium in the biliary tree seen on the first films.

The operation did not relieve the fundamental disease, and the patient finally died. Before death one more Hippuran injection demonstrated that the main radicle in the left lobe of the liver showed a filling defect consistent with stone. We do not know what the pancreas felt like at the third operation — it was probably impossible to feel it because of obliteration of normal structures.

The patient seemed to be suffering from liver failure. The white-cell count rose to 30,000. On the fourteenth postoperative day he suffered a minor trauma and finally died.

From the systemic point of view I believe that this patient had sepsis, nutritional depletion, dehydration and liver failure. Did he have some fundamental process, such as carcinoma, that was causing the entire picture? He could have had a carcinoma of the pancreas, I somehow believe that more concrete evidence would have been found in two surgical attempts in the right upper quadrant. If all this is blamed on carcinoma of the pancreas, it must be concluded that the obstruction to the duct was on that basis, and yet this was not so at operation.

Could the patient have had lymphoma or some other bizarre neoplastic process masking the sepsis? Reticulum-cell sarcoma often acts in that way, but such a diagnosis would be just a guess because we have no histologic evidence. There was an element of congestive failure. Terminally, I think that he

had cholemia, the clinical syndrome of liver failure, which can co-exist with a surprisingly low serum bilirubin, which in this patient seemed to be normal most of the time, but we must not forget that one lobe may have been obstructed while the other drained reasonably well.

What else could have caused the gradual downhill course? I cannot help thinking in terms of liver abscess. This patient had sepsis. We have no culture, but it may have been a virulent organism that was floating up and down the extrahepatic biliary tree for many months. The drainage was not adequate, and although liver abscess is much more commonly a blood-borne than a duct-borne lesion, I think that in this exceptional case, in which there was so much sepsis in and around the duct and evidence of at least anatomic obstruction of the duct, he may have had an abscess in the left lobe of the liver. If so, it would be less likely to show as a distortion of the diaphragm by x-ray study, because the left lobe of the liver is under the mediastinum instead of being under the free diaphragmatic structures.

My final diagnosis is heart disease, which I assume was arteriosclerotic in nature, with congestive failure, cholemia, sepsis around the common duct and liver abscess.

Dr. RAKER. One thing might be said about the hernial repair. The gastrointestinal series was originally interpreted as normal. The hernia was repaired, and it was not until after discharge that the final report came back showing this fistula.

Dr. MOORE. That is important. Such a delay happens all too frequently, simply because of a slow rapport between the services.

Dr. F. DENNETTE ADAMS. Why did you give up the thought—or rather why did you not concentrate on the thought—that the pancreas was involved as the result of chronic infection?

Dr. MOORE. One reason was that an amylase of 7 units per 100 cc. was recorded, and the level went back up to 48 units within a few weeks. It makes it seem unlikely to me that a great deal of scar tissue had been destroyed. There is no question that there was inflammation in the pancreas, but I doubt if a pancreatitis was the cause of the whole disorder. I have already mentioned my reasons for believing that although carcinoma of the pancreas was possible, it was an unlikely cause for the whole picture.

CLINICAL DIAGNOSES

Spreading peritoneal sepsis
Cholecystitis, with cholelithiasis, postoperative
Uremia

DR. MOORE'S DIAGNOSES

Arteriosclerotic heart disease, with congestive failure
Cholemia

Chronic cholangitis
Liver abscess

ANATOMICAL DIAGNOSES

Adenocarcinoma of body of pancreas, with extension into and ulceration of stomach
Choledochoduodenal cutaneous fistula
Pencholedochal abscess
Peritonitis, localized
Pneumonitis, aspiration type, bilateral
Diverticulum of duodenum
Diverticulitis and diverticulosis of sigmoid
Operations: cholecystectomy, old, choledochotomy, recent and old, left inguinal herniorrhaphy, old, bilateral, superficial femoral-vein ligations, old

PATHOLOGICAL DISCUSSION

Dr. MALLORY. The findings at autopsy were complicated. There were many adhesions throughout the abdomen, particularly around the region of the common duct and duodenum, and I am sure that that is what prevented exploration of the pancreas. There had been an acute sepsis about the common duct, which had been pretty well cleared up by the last operation. We did find one pocket of retroperitoneal pus above the upper pole of the right kidney and between the liver and kidney. That was relatively small, measuring 2.5 cm. in diameter. The fistula between the duodenum and the common duct was still present, and the ampulla was apparently perfectly patent, admitting a probe without difficulty. There was therefore no demonstrable obstruction of the biliary tract at the time of autopsy.

The heart showed a moderate grade of calcareous aortic stenosis, with considerable interadherence of the cusps and marked calcification, which would have prevented their complete opening.

The surprise of the autopsy was a large area of ulceration on the lesser curvature of the stomach, 4.5 cm. in one diameter and 3 cm. in the other. There was no suggestion of it in any of the x-ray studies. This was a deep ulcer, and the bed of the ulcer was formed by the pancreas. The pancreas seemed rather firm throughout but presented no areas of necrosis and no gross appearance of tumor. It was thought to be a chronic pancreatitis secondary to a penetrating gastric ulcer. When, however, we came to examine the microscopical sections, we were forced to change our minds drastically. Diffusely infiltrating through the pancreas was an adenocarcinoma, and the stomach was obviously secondarily involved by a cancer that was primary in the pancreas.

Dr. MOORE. It helps to demonstrate the truth of the old adage that if we lean too heavily on any one diagnostic aid—in this case x-ray examination—it may give way and let us down hard.

THANKSGIVING

IT HAS become a pleasant custom of the editorial writers of the *Journal* to comment on the annual return of certain significant holidays, and to recall what comfort or inspiration may be found in the occasion. The observance of Thanksgiving Day is particularly appropriate to this custom, for we think of our Thanksgiving, although a national holiday, as belonging especially to New England, where its celebration originated.

In 1621, after the first harvest of the Pilgrim Fathers had been gathered, Governor Bradford appointed a day of thanksgiving and prayer for the event. In 1623, during one of those extended droughts with which every New England farmer is familiar, a day of fasting and prayer was changed

into one of thanksgiving for the rain that fell even during the prayers that were raised in supplication for it. The Lord had let the light of His countenance shine upon the New World.

Soon all the New England colonies, by proclamation of their several governors, were observing a day of thanksgiving after their crops had been harvested and stored. The custom spread from New England. A Thanksgiving Day was annually recommended by the Continental Congress during the Revolution, and in 1864 President Lincoln inaugurated the custom, followed by each succeeding president, of proclaiming a general day of Thanksgiving for all the land.

Despite our tendency in this country to think of Thanksgiving as a uniquely American holiday (given to the rest of the nation by New England) there is no particular reason for cherishing a belief that the expression of gratitude, even to a higher power, had its origin in the Western Hemisphere. Noah, we are told, many years before the appearance of that other bold navigator, Columbus, erected an altar after his deliverance from the flood and offered thereon "of every clean beast and every clean fowl burnt offerings unto the Lord in Thanksgiving." The English, in November, 1588, thirty-two years before the Pilgrims set foot on Plymouth Rock, held their own first official Thanksgiving for the defeat of the Spanish Armada, with Queen Elizabeth in attendance.

So we too may recapitulate those facts for which we have reason to be thankful, but differing from the Pharisee who thanked God that he was not as other men nor even as the publican, preoccupied with his own humility. We may be thankful for that basic principle of equality that we recognize and cherish. We may be thankful that out of our abundance we are able and minded to help those from whom so much has been taken — that we, as physicians, are privileged for a while to carry the torch of learning and with it to kindle new fires in some of the lands where the light has come so close to extinction.

Let us be thankful at this season, not only for our possessions but for the desire to share them, not alone for security but for the courage to maintain it!

STUDY OF THE RUBELLA SYNDROME

AN AMAZING fact in the annals of modern medicine is the recent discovery of the relation between maternal rubella and the occurrence of certain congenital defects in the fetus. Apparently unheard of less than a decade ago, it has, in a surprisingly short time, become common knowledge that infection of a mother with rubella in the first trimester of pregnancy will result, in a large percentage of cases, in the occurrence of such defects as cataracts, deafness, microcephaly, mental deficiency and congenital heart disease in the fetus.

Such sinister sequelae from a virus infection so benign as rubella is generally considered to be are disturbing, they serve to increase still further our growing respect for virus diseases in general, and their possible late effects. Why this particular train of events has been hidden so long is a matter of conjecture. The relative infrequency of rubella and its usually mild manifestations in the age group involved, as well as the time interval between cause and effect, are probable factors.

More information is necessary before we have a clear picture of the effects of virus infection in the early months of pregnancy. Additional cases must be studied in which congenital malformations in the fetus have followed rubella in the mother, of particular importance will be figures on the incidence of rubella in early pregnancy *without* fetal complications, and a searching analysis of other types of virus disease to determine if they, too, may be involved in such a catastrophic sequence.

To this end a year's study has been launched and financed by the National Society for the Prevention of Blindness, Inc., with the approval of the American Academy of Pediatrics, and questionnaires are being sent to obstetricians, ophthalmologists and pediatricians, seeking pertinent information on the subject. Data will be collected on four types of cases: children with congenital defects associated with rubella in the mother during pregnancy, children without congenital defects whose mothers had rubella during pregnancy, children with congenital defects associated with other maternal infections in the first trimester of pregnancy, and children with the so-called "rubella syndrome" (cataracts, deafness, microcephaly and congenital

heart disease) unassociated with any maternal infection during pregnancy.

The occurrence of any such cases should be reported to Dr. Herbert C. Miller, University of Kansas Hospitals, Kansas City, Kansas, the chairman of the committee entrusted with the study.

MASSACHUSETTS MEDICAL SOCIETY
DEATHS

BAUM — Ewald G. Baum, M.D., of Natick, died on October 22. He was in his sixty-third year.

Dr. Baum received his degree from George Washington University School of Medicine in 1911. He was the inventor of a milk bottle cap to protect bottle tops from contamination. He was a fellow of the American Medical Association.

His widow, two stepchildren, a sister, two brothers and a nephew survive.

KING — Frederick A. King, M.D., of Marshfield, died on September 14. He was in his seventy-ninth year.

Dr. King received his degree from Boston University School of Medicine in 1895.

Two sons survive.

MASSACHUSETTS DEPARTMENT
OF PUBLIC HEALTH

MASSACHUSETTS STATE PLAN

The acute need for additional hospital facilities in this country resulted in 1946 in the enactment of Public Law 725, the Hospital Survey and Construction Act, by the Seventy-Ninth Congress. This act establishes a grant-in-aid program to assist the states to plan and build additional hospital and health-center facilities where they are most needed. In the next five years, under this program, total expenditures in Massachusetts alone will amount to twenty-four millions. Of this amount, a third will be allotted by the federal government and two thirds will come from state or local sources.

The Massachusetts plan for the administration of Public Law 725 is being developed in several stages. The first step consists of a survey of all existing hospitals and health-center facilities in the Commonwealth. After completion of the survey, the Commonwealth is divided into three categories of general hospital service areas designed as base, intermediate and rural, depending on population and the existing or proposed general-hospital facilities within the area. The next step is the determination of general bed needs by formulas established by the United States Public Health Service for each type of area that leads to the establishment of a priority schedule. The order of general-hospital projects built under this act must conform with this priority scheme. Finally, consideration is given to the determination of needs in the other categories of facilities — that is, tuberculosis, mental and

—by standards established by the United States Public Health Service

After approval of this plan by the State Advisory Council and the Surgeon General of the United States Public Health Service, a construction program will be developed for a five-year period in which federal funds will be distributed among the five categories of facilities mentioned above

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR SEPTEMBER, 1947

DISEASES	RÉSUMÉ		
	SEPTEMBER 1947	SEPTEMBER 1946	SEVEN-YEAR MEDIAN
Chaneroid	2	1	1*
Chicken pox	123	110	106
Diphtheria	10	50	10
Dog bite	960	1079	924

Undulant fever	10	1	2
Whooping cough	646	520	520
*Three-year median			
†Five-year median			

COMMENT

Diseases above the seven-year median were chicken pox, dog bite, poliomyelitis, salmonellosis, undulant fever and whooping cough

Diseases below the seven-year median were bacillary dysentery, German measles, gonorrhea, malaria, measles, meningococcal meningitis, mumps, lobar pneumonia, scarlet fever, syphilis, tuberculosis and typhoid fever

The downward trend of diphtheria has continued since June, 1947, so that it is now at the seven-year median. It is unlikely that this low prevalence will be maintained unless more energetic immunization programs are carried on.

Poliomyelitis is the highest recorded for the year — an incidence of 149 cases in September compared to 80 in August and 21 in July. The peak for the season appears to have been reached.

There is an indication that the upward trend in whooping cough, which had halted during the summer, is being resumed.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Ashburnham, 1, Bolton, 1, Boston, 7, Westfield, 1, total, 10.

Dysentery, bacillary, was reported from Boston, 1, Lexington (Metropolitan State Hospital), 6, Malden, 2, Salem, 2, Worcester, 1, Wrentham (State School), 2, total, 14.

Encephalitis, infectious, was reported from Salisbury, 1, Quincy, 1, Wareham, 1, total, 3.

Malaria was reported from Boston, 2, Braintree, 1, Everett, 1, Malden, 1, Seekonk, 1, Worcester, 1, total, 7.

Meningitis, meningococcal, was reported from Fall River, 1, Lowell, 1, Wellesley, 1, total, 3.

Meningitis, pneumococcal, was reported from Melrose, 1, total, 1.

Meningitis, streptococcal, was reported from Taunton, 1, total, 1.

Meningitis, other forms, was reported from Amesbury, 1, total, 1.

Meningitis, undetermined, was reported from Fall River, 1, Middleboro, 1, Newton, 1, North Attleboro, 1, Norwood,

1, Pittsfield, 2, Sheffield, 1, Warcham, 1, Wrentham, 1, total, 10.

Poliomyelitis was reported from Andover, 1, Arlington, 3, Athol, 1, Barnstable, 1, Becket, 1, Bellingham, 1, Beverly, 1, Boston, 23, Braintree, 1, Bridgewater, 1, Brockton, 2, Brookline, 9, Cambridge, 5, Canton, 1, Concord, 2, Dartmouth, 2, Dedham, 4, Egremont, 1, Everett, 1, Fall River, 7, Freetown, 1, Greenfield, 1, Hingham, 3, Lowell, 1, Lynn, 6, Marshfield, 1, Medford, 2, Middleboro, 2, Milton, 3, Natick, 2, New Bedford, 2, New Marlboro, 2, Newton, 3, North Brookfield, 1, Quincy, 2, Reading, 2, Revere, 1, Salem, 1, Saugus, 1, Sheffield, 2, Somerset, 1, Somerville, 2, Southbridge, 1, Springfield, 2, Sudbury, 3, Taunton, 3, Templeton, 1, Tewksbury, 1, Wakefield, 1, Waltham, 3, Watertown, 1, Wayland, 1, Wellesley, 2, West Bridgewater, 1, West Springfield, 1, Westport, 1, Weymouth, 1, Winchendon, 1, Winthrop, 1, Worcester, 10, total, 149.

Salmonellosis was reported from Andover, 1, Attleboro, 1, Boston, 2, East Bridgewater, 1, Gloucester, 1, Holyoke, 4, Lawrence, 1, Lowell, 3, Lynn, 1, Marblehead, 1, Medford, 3, Monterey, 1, Newburyport, 1, Salem, 2, Saugus, 1, Templeton, 1, total, 25.

Septic sore throat was reported from Amesbury, 1, Boston, 3, Haverhill, 1, Quincy, 1, total, 6.

Tetanus was reported from Brockton, 1, Great Barrington, 1, total, 2.

Trachoma was reported from Wakefield, 1, total, 1.

Trichinosis was reported from Boston, 1, Fall River, 2, Falmouth, 1, total, 4.

Typhoid fever was reported from Shrewsbury, 1, total, 1.

Undulant fever was reported from Bedford, 1, Belcher town, 1, Fitchburg, 1, Greenfield, 1, Holyoke, 1, Mansfield, 1, Palmer, 1, Somerset, 1, Warren, 1, Weston, 1, total, 10.

CORRESPONDENCE

NATIONAL PHYSICIANS COMMITTEE

To the Editor: A recent communication from the National Physicians Committee entitled "Factual Memorandum" says, "The source of the unremitting and relentless drive for Compulsory Health Insurance — Socialized Medicine — the Political Distribution of Medical Care in this country — is the Moscow dominated Communist Party of the United States."

The facts in regard to attempts to develop a National Health Program to be financed by compulsory health insurance are as follows. In 1938 President Franklin D. Roosevelt called a National Health Conference in Washington following which the first Wagner-Murray-Dingell Bill for Compulsory Health Insurance was introduced in 1939. This was followed by similar bills introduced by the same gentlemen in 1943 and 1945. On November 19, 1945, President Harry S. Truman requested legislation for adoption of a National Health Program, and at the same time Senators Wagner and Murray and Representative Dingell introduced a fourth bill entitled The National Health Act of 1945. Hearings were held on this bill before the Senate Committee on Education and Labor in the Spring of 1946, during the course of which Senator Taft supported by the American Medical Association and the National Physicians Committee introduced a bill entitled The National Health Act of 1946. Finally in the present Congress there are two health bills, one introduced by Senators Taft, Smith, Ball and Donnell in February, 1947, entitled The National Health Act of 1947, S. 545, and the other by Senators Murray, Wagner, Pepper, Chavez, Taylor and McGrath in May, 1947, entitled The National Health Insurance and Public Health Act of 1947, S. 1320. Thus it becomes apparent that both political parties now favor a National Health Program of some sort, and the question is, What will be the best program?

Both these bills of course are equally compulsory, the former requiring compulsory contributions to general taxes, and the other compulsory payroll contributions. Neither bill is compulsory as regards the receipt or the giving of medical services.

The main difference between the two bills is that the one favors the raising of the major part of the funds by the insurance principle from employed people and only using general tax funds to cover the needs of the unemployed. This eliminates the problem of administering a costly means

test. It provides that the majority of people will be paying for their care and not getting free medicine. The other bill calls for the delivery of medical care paid for by taxes as charity after a means test has established the individual's eligibility. This means the recipients will be getting free care. As medical care is bound to become more expensive, this program will almost inevitably include an ever increasing proportion of the population. Even today fifty per cent of the people would probably claim and qualify for eligibility for part of their medical care. Thus the Taft Bill is just as much "Socialized Medicine" as the Wagner Bill. Indeed Ex Governor Arnall characterizes it as Bismarckian state socialism of the most paternal type.

The idea of a National Health Program financed by Compulsory Health Insurance which was originated by President Franklin D. Roosevelt and furthered by President Harry S. Truman is now openly supported among others by the following groups of our citizens: American Association of Social Workers, Americans for Democratic Action, American Federation of Labor, American Veterans Committee, Congress of Industrial Organizations, Cooperative League of the United States of America, Council for Social Action of the Congregational Christian Churches, Methodist Federation for Social Service, National Association for the Advancement of Colored People, National Federation of Settlements, National Catholic Welfare Conference, National Consumers League, National Council of Jewish Women, National Council of Negro Women, National Farmers Union, Committee for the Nation's Health Inc., Committee of Physicians for the Improvement of Medical Care, Inc. and The Physicians Forum Inc.

It must seem absurd to any intelligent person that two presidents of the United States and the above groups could be under the control of the Moscow-dominated Communist Party of America. It is hard for me to believe that the National Physicians Committee honestly thinks so. Therefore, I am forced to the conclusion that this Committee is either grossly ignorant of the facts or actually trying to misinform the medical profession. This suspicion that the National Physicians Committee whose actions have been approved by the House of Delegates of the American Medical Association knowingly circulates misinformation is strengthened by its actions in the past.

In the publications of the hearings before the Committee on Education and Labor, United States Senate, 79th Congress, Second Session on S. 1606 Part 5, page 2679, seven quotations from the literature circulated by the National Physicians Committee are included and in each instance are proved false by quotations from the *Journal of the American Medical Association*. An example follows: "The statement by the National Physicians Committee 'The doctor would have little if any interest in the patient who is compelled to visit him'." Refutation by quotation from the *Journal of the American Medical Association*: "A patient may select any doctor." The other six misstatements recorded are as simply refuted by the *Journal of the American Medical Association* as the above. It is of interest that no denial of the accuracy of these senatorial records showing the falsity of statements by the National Physicians Committee has been forthcoming.

If the medical profession of this country wishes to form an honest opinion in regard to the relative value of the National Health Program under discussion it seems only fair that it should be permitted to judge the issue from statements of fact rather than from misrepresentations broadcast by the National Physicians Committee. Yet the tragic truth is that in the medical journals throughout the country with the exception of the *New England Journal of Medicine* and the *Official Journal of the American Academy of Pediatrics* little if any opportunity is offered for presentation of opinions other than those of the House of Delegates of the American Medical Association.

Physicians must be alert not to be deceived about the actual facts of proposed National Health Programs by the false statements of the National Physicians Committee. The subject is of vital importance to physicians. It deserves serious consideration not prejudiced propaganda.

BOOK REVIEW

The Development of Inhalation Anesthesia to the Year 1846-1847
(Oxon) Publications of the Museum 8" cloth w/ Oxford University Press 1

The centennial of either an event last year of several volumes such as Dr. Rapaport's *Factory over Paris* and the by the reference librarian for the to these the present volume, second publications by the Wellcome History is an official British history of the device. The author as a member of the Nu Anaesthesia of the University of Oxford tootory of research for this study and has att to trace the beginnings and to follow the those concepts and practices which have gone of the science and art of inhalation anaesthetic to show how current beliefs and happenings "evolution." The volume is well illustrated with 28 lung is and sixty-one engravings preacots a number from case topics in a series of five appendices and closes with a summary of events in the history of anaesthesia. Priestley's discovery of nitrous oxide in 1772 to hysema study in 1911 of ventricular fibrillation under chloro Dr. Duocum writes with authoritative scholarship. She made a distinguished and valuable contribution to medical history.

The Psychoanalytic Study of the Child Volume II 8" cloth 424 pp. New York International Universities Press 1947 \$7.50.

This book is a collection of papers, some original and some revised on a wide variety of topics in psychoanalysis. The factual data concerning psychoanalytic findings and therapy in children or adolescents are meager in proportion to the quantity of strictly nonpediatric discussions and formulae. If the reader is to believe that in the book was gathered material for bringing up to date the workers in psychiatry and related fields in child psychoanalysis, the bibliographies at the end of each chapter (each presentation) are for the most part rather old. This gives the impression that each author has picked on a highly specialized topic on which to expound. Each paper is set apart from the others making the book uncohesive and many items are repeated. Some discussions are polemic—for example that on page 324 in which Harbs are thrust at Klein, Adler, Jung and others.

The case reports were unusually well written, interesting and instructive. They illustrated the necessary titled features quite closely.

Although some of the material is new, much of the matter discussed has previously been presented in the periodic literature and standard texts concerning psychoanalysis. To the reviewer the book appeared to be an overused journal emphasizing by implication certain features of child and adolescent psychiatry.

The Postnatal Development of the Human Cerebral Cortex By J. LeRoy Conel M.D. Cambridge, Massachusetts Harvard University Press, Volume I (1939) *The Cortex of the Newborn* 8" cloth 106 pp., with 2 tables and 194 illustrations \$8.00. Volume II (1941) *The Cortex of the Old Infant* 8" cloth 136 pp., with 3 tables and 270 illustrations \$8.00. Volume III (1947) *The Cortex of the Three-Month Infant* 8" cloth 148 pp., with 6 tables and 219 illustrations \$12.50.

The first three volumes of this monumental contribution by Dr. Conel on the postnatal development of the human cerebral cortex begun in 1939 have been published by the Harvard University Press. The printing of these studies was made possible by a grant from The John and Mary R. Markle Foundation as well as by contributions from various research funds. The work has been conducted at Boston School of Medicine, Harvard Medical School Children and Infants hospitals in Boston.

THE PATHOGENESIS OF BRONCHIECTASIS*

TRACY B. MALLORY, M.D.†

BOSTON

SINCE Laennec¹ first described and named bronchiectasis its etiology and mode of development have been controversial issues. Numerous theories have been advanced, each of which is backed by voluminous evidence, but no one of which satisfactorily explains all types or features of the disease. Either the underlying cause remains undiscovered or multiple factors exist that predispose to or result in dilatation of portions of the bronchial tree. I propose, in the short time at my disposal, to review briefly the more significant of these possible factors and to compare their relative importance and interrelation.

Four important clinical and anatomic features of the disease must be explained by any theory of pathogenesis that can be considered satisfactory. First, bronchiectasis is rarely a diffuse disease of the bronchial tree. It characteristically involves a group of adjoining bronchi such as those of a lobe or a portion of a lobe—for example, the lingula of the left upper lobe. The affected segments of the tree may be, and frequently are, multiple but bronchi in the uninvolved areas are entirely normal.

Secondly, bronchiectasis is not usually a progressive disease. Most cases come under observation with well developed segmental involvement, and over months or years no extension to other portions of the bronchial system will be apparent unless an attack of pneumonia supervenes, when another segment may become involved.

Thirdly, bronchiectasis is rarely seen as an isolated finding in an otherwise normal lung. The surrounding pulmonary parenchyma is characteristically although variably abnormal. In the earlier literature, based primarily on post-mortem studies, acute and chronic pneumonitis was usually recorded, and Lord² was so impressed with parenchymal involvement that he preferred the term "bronchopulmonary sepsis" to bronchiectasis. In the present era, when lobectomy specimens are available from which to

study earlier stages of the disease, septic pneumonitis is unusual, but the surrounding lung is rarely normal. The changes vary widely from case to case, however, and may comprise atelectasis, fibrosis, organized pneumonitis, focal emphysema or even total destruction of alveolar tissue.

Fourthly, although bronchiectasis can develop at any age, it is characteristically a disease of youth. Onset in the first decade was recorded in 42 per cent of Perry and King's series, and 69 per cent of their patients developed the disease before twenty years of age. With these four points in mind, the various theories of pathogenesis will be considered.

CHRONIC BRONCHIAL INFECTION

Bronchiectasis is ordinarily associated with a chronic productive cough, and the sputum is characteristically abundant and purulent. In the days before modern contrast radiography with lipiodol instillation the evidence of bronchitis frequently preceded by long intervals the physical signs or x-ray appearance that would permit the diagnosis of bronchiectasis. Moreover, in autopsy or even resected specimens, evidence of chronic infection of the bronchial walls was almost uniformly present. The assumption that bronchial infection was primary and induced bronchial dilatation by injury to the skeletal structures of the bronchial walls, the musculoelastic tissues and the cartilaginous rings was not unreasonable. The chronic cough was thought by some to have a dilating effect on the bronchi, despite the fact, as Andrus³ points out, that during cough the pressure is greater in the alveoli than in the bronchi, which therefore tend to be compressed rather than dilated. The deep inspiration preceding cough has, it is true, a bronchodilating effect but is of such brief duration that its effect is probably unimportant. The pressure of stagnant secretions was proposed by Laennec¹ himself as a dilating agent, but of course cannot be a factor in the "dry" types of bronchiectasis in which no secretion is present over long periods.

If ordinary bronchitis were a frequent cause of bronchiectasis one would expect the disease to be,

*Part of a symposium on bronchiectasis presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1947.

1. Director, Department of Pathology and Bacteriology, Massachusetts General Hospital.

like emphysema, a geriatric rather than a pediatric problem. Many efforts have consequently been made to isolate specific organisms of exceptional virulence or of peculiar histolytic properties that would explain the extensive destruction of bronchial walls. Such attempts have been entirely unsuccessful.⁶ The organisms found in bronchiectatic secretions are variable, numerous and usually mixed. Staphylococci, streptococci of numerous types and *Haemophilus influenzae* are usually present, spirochetes and fusiform bacilli are sometimes seen, and a wide variety of other organisms may be found from case to case and even from time to time in the same patient. Entirely similar flora may be observed in bronchitis without bronchial dilatation.

Careful pathological studies by Robinson^{7, 8} of the affected bronchial walls in a series of lobectomy specimens showed the constant presence of severe inflammatory infiltration. Frequently, these infiltrates surrounded or invaded the scanty remnants of the musculoelastic tissues and the cartilaginous rings. These pictures were interpreted as evidence of active destruction of these elements by the inflammatory process. In a survey of lobectomy specimens I found severe bronchial inflammation of the type described by Robinson in 35 of 50 cases. In the remainder the inflammation was comparatively mild and in a case of so-called "dry bronchiectasis" was entirely absent. There was no close parallelism between the severity of inflammation and the degree of bronchial dilatation. Moreover, in a series of lungs from patients who had suffered from chronic asthma, in which no dilatation of bronchi was present and in which inflammatory infiltration sometimes exceeded that found in frank bronchiectasis, active necrotizing bronchitis was observed in only 3 cases. Its absence at the time of lobectomy does not, of course, deny the possibility of its existence in the past. When allowance is made for the stretching and atrophic effects of chronic dilatation it is doubtful if the evidence for active destruction of bronchial structures is adequate in most cases.

CONGENITAL ABNORMALITIES

The most important of the congenital abnormalities is the condition termed "congenital cystic disease." Outgrowths or buds of bronchial tissues from the trachea and major bronchi into the tissues of the mediastinum are not infrequent. These may produce cysts lined with ciliated or pseudostratified epithelium and may contain in their walls varying amounts of muscle, cartilage and glandular tissue. If the lumen of the stalk is obliterated they become distended with mucinous fluid.

That similar bronchial outgrowths that fail to differentiate into alveolar tissue may develop within the lung itself is not improbable, and lung cysts with or without connection with the lumen of bronchi have frequently been described.⁹⁻¹¹ The criteria for their recognition, however, are far from adequate,

and nearly all the features considered characteristic of congenital cystic disease are seen from time to time in bronchiectases that are almost certainly acquired. The existence of congenital cystic disease cannot be denied, but it seems probable that the diagnosis has been made far too frequently and with insufficient realization of how early in infancy and childhood acquired bronchiectasis may develop.

An indirect result of congenital influence is clearly shown by the cases of situs inversus with bronchiectasis of the lower lobe and coincident sinusitis.¹² The contention of Sauerbruch¹³ that many patients destined to develop bronchiectasis have inherited bronchial defects is difficult to disprove but lacks positive supporting evidence.

BRONCHOSTENOSIS

Stenosis of major bronchi is frequently associated with progressive ectasia of the subtending divisions. Aspirated foreign bodies, intrabronchial tumors such as adenomas and slowly growing carcinomas, bronchial cicatrices due to syphilis or tuberculosis and peribronchial pressure from enlarged hilar lymph nodes, such as the primary complex of tuberculosis, have frequently been reported as initiating factors in the development of bronchiectasis.¹⁴ Their influence cannot be denied, but the assumption of a direct causal relation is not necessarily valid. Fleischner,¹⁴ in an interesting paper, reports 3 examples of bronchostenosis, the first associated with emphysema but no bronchial dilatation, the second with moderate ectasia but abundant purulent sputum and the third with extreme bronchial dilatation but no evidence of inflammation. Eloesser,¹⁶ in a very thoughtful discussion of bronchostenosis, emphasizes the importance of Conner's¹⁶ review of tracheobronchial syphilis. Although obstruction was present in nearly all cases only 15 per cent showed bronchial dilatation, and in 2 cases the bronchiectasis was limited to a portion of a lobe even though the stenosis was in the primary bronchus.

Another important group of cases to be considered in relation to the effects of bronchostenosis consists of the chronic asthmatic patients. In these patients functional narrowing of the bronchi exists over many years. In a group of 60 such cases that I have personally studied bronchiectasis was so exceptional that it appeared coincidental, although emphysema and cor pulmonale were of common occurrence.

Stenosis of bronchi, therefore, evidently does not regularly induce dilatation of the distal branches. If the obstruction is incomplete and expiration is impeded more than inspiration the alveoli rather than the bronchi tend to dilate, and emphysema results. With complete obstruction atelectasis follows, and this, as demonstrated below, is an important factor in the development of bronchial dilatation. Bronchostenosis, like obstruction in other duct

systems of the body, is also an important factor in the development and chronicity of infections, and infection of bronchi and of pulmonary parenchyma is another significant factor in the development of bronchiectasis. Finally, although a contributory role cannot be denied to bronchostenosis in many cases, the great majority of bronchiectatic lungs show no evidence whatever of narrowing of the bronchial tree proximal to the areas of dilatation.

ATELECTASIS

To the radiologists and the pediatricians we owe a group of very important studies linking the development of bronchiectasis with persistent atelectasis.¹⁷⁻²⁰ Anspach¹⁷ in particular has called attention to the frequency in infancy and childhood of a triangular shadow at the base of the lung field due to persistent atelectasis of a lower lobe or a large segment of such a lobe. Bronchograms following lipiodol injection regularly show dilatation of bronchi throughout this atelectatic area. In cases in which bronchoscopic drainage or other appropriate treatment is successful in relieving the atelectasis the bronchi may revert to normal. More frequently, however, the ectasia is already irreversible when first observed. Similar observations of reversible bronchial dilatation associated with atelectasis have been described by Singer and Graham²¹ under the term "pseudobronchiectasis."

The mechanism by which atelectasis induces bronchial dilatation has been discussed in detail by Andrus⁴ and others.²² With collapse or destruction of huge amounts of pulmonary parenchyma a potential space is created within the pleural cavity, and the negative intrapleural pressure increases from a normal of -4 to -6 mm to figures as great as -30 to -40 mm. Numerous compensatory factors are brought into play. The chest wall is relatively rigid, but the diaphragm rises, the mediastinum shifts toward the affected side, and the neighboring pulmonary tissue overexpands. Despite these adjustments the intrapleural pressure remains more negative than normal, and this negative pressure is transmitted through the solid nonexpanded pulmonary tissue to the elastic and expandable bronchial walls. Here at last one finds an effective dilating force, which is constant for the duration of the atelectasis.

It must be emphasized that it is not atelectasis *per se* that tends to dilate bronchi but the effect of the exaggerated negative intrathoracic pressure. In therapeutic pulmonary collapse, when air is periodically introduced into the pleural cavity and negative pressures do not develop, pulmonary atelectasis may be maintained for long periods without danger of bronchial dilatation.

Strong opponents of the theory that atelectasis induces bronchiectasis are Tannenbergs and Pinner.²³ In carefully carried out experiments in rabbits atelectasis was produced by several means. Bron-

chiectasis did not develop unless the bronchi were simultaneously infected. It is by no means certain, however, that experiments on a small quadruped can fairly be used in drawing conclusions regarding man.

PNEUMONIA AND OTHER FORMS OF PNEUMONITIS

In all reports of series of bronchiectatic cases histories of pneumonia or of upper respiratory infections frequently complicated by pneumonia, such as measles, pertussis and influenza have been obtained in 50 per cent or more of the patients (Ballou, Singer and Graham,²⁴ Perry and King² and Ogilvie²⁵). Unfortunately, the nature of the pneumonic process can rarely be established from the available data. It is certainly unusual to see a typical pneumococcal pneumonia progress to bronchiectasis. In contrast, Opie and his associates²⁶ described the development of acute bronchiectasis following the 1918 influenza epidemic, and Kay²⁷ has recently reported 20 cases that were the sequel to atypical pneumonia in World War II. A significant number of patients trace the onset of their disease to a tonsillectomy, and another group to aspiration of foreign bodies — both common causes of septic pneumonia. In autopsy and in resected specimens extensive inflammation of the pulmonary parenchyma is frequently observed, or patches of fibrosis may permit one to infer its presence in the past. In many cases, however, there is nothing to suggest the possibility of antecedent pneumonia.

DISCUSSION

Five factors — direct bronchial infection, congenital malformation of the bronchial tree, bronchial stenosis, pulmonary atelectasis and pneumonia, with its sequel, pulmonary fibrosis, — have been discussed in relation to the pathogenesis of bronchiectasis. It has been shown that there is positive evidence to indicate a causal relation in certain cases for each of the five but that no one of them is

TABLE 1 Factors Present in 50 Cases of Bronchiectasis

FACTOR	TOTAL CASES	SEVERE GRADE	SOLITARY OCCUR REPER
Bronchitis	49	35	0
Atelectasis	43	24	0
Pneumonitis	41	19	0
Fibrosis	40	3	0
Bronchostenosis	3	1	0
Emphysema	6	0	1

constant or can explain all cases. The complexity of the situation is shown by Tables 1 and 2, which were prepared from a survey of fifty unselected lobectomy specimens. No case considered to be of congenital origin appeared in the series, and bronchostenosis was present in only 3 cases.

It is evident from Table 1 that bronchial inflammation, atelectasis, active pneumonia and fibrosis

were each present in 80 or more per cent of the specimens but that no one of these factors was constant and no one of them was ever a solitary finding unassociated with at least one other of the group. The combinations varied as is shown in Table 2.

It may safely be concluded that acquired bronchiectasis is generally a disease of the pulmonary

parenchyma, as well as of the bronchial tree itself. This parenchymal involvement varies in detail, but one feature is common to all varieties: a noteworthy reduction in the number of aerated alveoli, potentially reversible in cases of atelectasis or early pneumonitis and certainly irreversible in cases of pulmonary fibrosis. Such a reduction in aerated parenchyma lowers the intrathoracic pressure and thereby generates an effective dilating force on the bronchial walls. The lack of aerated alveoli behind the involved bronchi renders cough ineffective as a mechanism for clearing bronchial secretions, since no current of air is generated, and stagnation of secretions becomes inevitable in dependent bronchi.

The assumption of primary bronchitis and secondary atelectasis with or without pneumonitis meets the test of the four criteria proposed above. Bronchial infection may cause atelectasis by obstructing the aeration of the alveoli with mucopurulent secretions. Infants and children are particularly prone to such obstructive atelectasis because the collateral air circulation through the pores of Kohn does not develop until adult life. They are also susceptible to pulmonary infections, in which bronchitis and atelectasis are more frequent than true pneumonic consolidation. Atelectasis is most likely to develop in the lower or middle lobes and in the lingula of the left upper lobe — the same distribution in which bronchiectasis is most usual. The most hopeful prophylactic measure in the prevention of bronchiectasis is therefore the prevention or prompt alleviation of atelectasis.

SUMMARY

Five factors — chronic bronchial infection, congenital abnormalities of the bronchial tree, broncho-stenosis, pulmonary atelectasis and pneumonitis or its sequel, pulmonary fibrosis — have been shown to be potential factors in the etiology of bronchiectasis. Of these, congenital cystic disease and broncho-stenosis are comparatively uncommon. Bronchial inflammation alone is rarely an effective factor but in combination with atelectasis or pneumonitis adequately accounts for most of the characteristic features of the disease.

AMEBIASIS

JOSEPH H. NICHOLSON, M.D. * AND FRANK A. DE DOMINICIS, M.D. †

BOSTON, MASSACHUSETTS, AND PATERSON, NEW JERSEY

NOW that World War II is over, it will be well to remember that a large part of the armed forces have seen service in areas heavily infected with *Endamoeba histolytica*. Most of these men and women have returned to their homes in the United States. A certain portion of them will have become infected with *E. histolytica*. The long incubation period of amebiasis, the comparatively mild nature of its symptomatology in many cases, the long period of symptom-free remissions and its tendency to recur merely emphasize the necessity that its presence be recognized. It is essential to realize not only that this disease may occur in returning veterans but also that cross-infection occurs in temperate zones and that the symptomless carrier, as well as the mild unrecognized case, serves as a reservoir of infection of the civilian population.

In the northeastern states amebiasis has always been endemic. Although several surveys of sample populations by the method of stool examination indicate that from 5 to 10 per cent of the people at some time harbor *E. histolytica* in their intestines, Faust¹ expressed the belief that an average incidence as high as 20 per cent, rather than the accepted figure of 5 to 10 per cent, may be reached in the United States. Table 1 presents the cases of amebic dysentery observed in Massachusetts from 1935 through 1945.² In 1944 and 1945 all cases but 1 were reported from the Army medical installations stationed in Massachusetts. In the years 1938–1939 Maine and New Hampshire reported only 1 case of amebiasis each. New York, in the same years, reported 153 cases. In 1937 Brenner³ described 15 cases of amebiasis seen at the Peter Bent Brigham Hospital. In these cases one third of the patients had contracted the infection in New England.

That amebiasis is prevalent in the temperate zones and is not a disease limited to the tropical areas has repeatedly been emphasized. Judging by the paucity of reported cases in New England, one is led to believe either that the disease is not being recognized or that it is not being reported. It is our opinion that both beliefs are probably true. In any event, the war has created a much greater reservoir of people infected with *E. histolytica* who live in temperate zones. It is therefore considered timely to stress some of the clinical aspects of cases studied that are of value in the diagnosis of this disease. The clinical aspects of 60 cases of amebiasis seen in the Lovell General Hospital from January,

1945, to June, 1946, are presented below. The patients have been discharged from the Army and reside in the following states: Massachusetts (32 patients), Connecticut (12 patients), New York (7 patients), Maine (4 patients), Rhode Island (3 patients) and New Hampshire (2 patients).

The duration of symptoms varied from a few days to eleven years, one patient having had symptoms referable to the colon that had been present for the latter period of time. This case had previously been diagnosed as an "irritable colon." It was of interest that the symptoms occurred after a visit to the World's Fair in Chicago in 1933. There is some question, however, whether the symptoms were entirely due to amebic infestation, for in the last month they had become more marked. It was only at that time that stool examinations were done and cysts of *E. histolytica* found. There was a complete remission of symptoms following a course of Diiodoquin. It would have required a longer period of observation, which was not possible in this case, to ascertain whether the symptomatology was entirely due to infection with *E. histolytica* or whether there was some underlying psychogenic disturbance. Symptoms were present for periods of less than three months in 12 cases and from three months to one year in 29. In 18 cases, symptoms were present for longer than one year.

The most frequent symptom was diarrhea (Table 2). In 25 cases the diarrhea was bloody. This varied from frankly bloody to merely blood-streaked stools. In a few cases there was rectal bleeding following defecation simulating that frequently seen in bleeding hemorrhoids. In 27 cases the stools were nonbloody, they were generally watery and brown. A fairly large percentage of these stools contained variable amounts of mucus. The severity of the diarrhea differed considerably. The number of stools varied from one to twenty a day. The patients often stated that the stools were normal between attacks of diarrhea. On close questioning, however, it was found that the stools were not of the same consistence as those prior to the onset of the diarrhea, but were somewhat loose and mushy.

The next most frequent symptom was abdominal pain. The pain was generally mild although in a few cases it was rather severe. In most cases it was low abdominal or periumbilical. It was generally described as crampy and was often relieved by defecation. In a few cases the pain was epigastric and closely simulated that of a peptic ulcer. In only 1 case was abdominal pain present without an associated diarrhea. In 7 cases there was a

*Assistant in medicine, Tufts College Medical School.

†Formerly ward officer, Medical Section, Lovell General Hospital, Fort Devens, Massachusetts.

history of right-upper-quadrant pain All these patients had liver involvement and are discussed in detail below We have not included under abdominal pain 5 patients who complained of epigastric distress but have listed that symptom separately

Loss of weight was a prominent symptom, occurring in 11 cases The weight loss varied from 10

Constipation	3
Alternating diarrhea and constipation	2
Pain in rectum and coccyx	2
Joint swellings	1
Hemoptysis	1

which also probably played a part in the weight loss Nausea, anorexia and vomiting were the next most prominent symptoms Nausea and vomiting occurred only in association with either diarrhea or abdominal pain Less frequent symptoms were fatigability, dyspepsia, feverishness and chills The last two were present only in patients with liver involvement In 3 cases constipation was the only change in bowel habit and was not associated with diarrhea Chest pain, joint swelling and hemoptysis occurred as the presenting symptoms in 1 patient

with amebic liver abscess and bronchohepatic fistula In 2 cases the patients complained of alternating diarrhea and constipation

Physical examination offered little help in the diagnosis of amebiasis, except in patients with amebic hepatitis or liver abscess (These cases are discussed below) A few patients had some tenderness in either the right or the left lower quadrant, or both, but it was hardly diagnostic. In 1 case there was a perianal fistula In another there was evidence of bronchohepatic fistula with pulmonary involvement In no case were masses palpated Evidence of weight loss was present in 11 cases In the cases without hepatic involvement there was elevation of temperature in only 2 cases, the temperatures being 101 and 102°F

Proctoscopic examination was done in 47 cases There were minute mucosal hemorrhages of the rectum in 5 cases, in 2 of which trophozoites were obtained from scrapings In another case, cysts were observed in the stool but not in the scrapings In the 2 remaining cases, both stool examination and scrapings failed to reveal either cysts or trophozoites Seven cases showed the typical proctoscopic picture of amebic dysentery — namely, a sharply punched out ulcer crater, with undermined margins and with normal mucosa intervening In this group, motile trophozoites were obtained from the ulcers in 3 cases In 2, cysts were recovered The remaining patients failed to reveal either cysts or trophozoites Routine examination of the stools showed evidence of cysts in 1 case There were 8 cases of ulceration with generalized inflammation of the rectosigmoid mucosa in which scrapings from the ulcerated area failed to disclose cysts or motile trophozoites Cysts were found on routine stool examination in 3 cases, however, and the remainder showed neither cysts nor trophozoites In 1 patient, there was ulceration, with diffuse granulomatous changes Scrapings failed to reveal either cysts or trophozoites, and stools were repeatedly normal All these patients received active therapy, and repeated proctoscopic examinations were done on all, after the treatment there was complete healing

Reports of incidence of positive proctoscopic findings in amebic dysentery have shown marked variance Jackman and Cooper⁴ observed lesions in 21 per cent of 115 patients Manson-Bahr,⁵ on the other hand, found that 90 per cent of 258 patients had positive proctoscopic findings An intermediate figure of 42 per cent positive proctoscopic findings was reported by Browne et al⁶ In our group of 60 cases 47 patients had proctoscopic examinations, and of these 43 per cent had positive findings

Repeated stool examinations were done on all patients The stools were examined by direct fecal film and also by the zinc sulfate flotation technic In many cases, the specimens were plated for isolation of *Shigella* organisms As many as fifteen stool

examinations were done on some patients. During proctoscopic examination, warm-stage microscopical studies were made of scrapings from the rectal or sigmoid mucosa for trophozoites.

Stools were positive in 46 cases. Of these, 38 showed cysts, and 8 disclosed motile trophozoites of *E. histolytica*. The location and forms of the organisms are presented in Table 3.

White-cell counts, which were taken on all the patients, ranged from 4000 to 10,000 in all cases uncomplicated by liver involvement, except in 1 in which the count was 12,000. The counts in cases of hepatic involvement are discussed below. The differential counts of white cells in the nonhepatic cases were within the normal range except for eosinophilia in 4 cases. The eosinophil count was 10 per cent in 2 cases and 16 per cent in 2 others.

Barium enemas were administered to 28 patients. In this group 19 patients failed to show any abnormalities, and 9 revealed changes on x-ray study. Of these, 2 disclosed spasticity of the entire colon, and 3 spasticity and irregular narrowing of the lower descending colon and sigmoid. One patient showed spasticity of the colon with loss of normal haustral markings to the hepatic flexure and with rigidity of the lower sigmoid. Cecal irregularity was noted in 4. Of the 9 cases with abnormal roentgenologic findings, there were cysts in the stools in 5. No motile trophozoites were found in any of these cases. Proctoscopic examinations in this group were positive in 4 cases, with pin-point hemorrhage in 2, ulceration with normal mucosa intervening in 1 and ulceration with generalized inflammation of the intervening mucosa in 1. In the cases with cecal irregularity, there was normal rectosigmoid mucosa in 3 and evidence of pin-point hemorrhage in 1. Stools were positive for cysts in 1 of these cases.

Considering the extent of literature published about amebic dysentery, comparatively little has been written about the roentgenologic aspects of the disease. Vallarino⁷ was the first to call attention to the roentgenologic findings. More recently, Weber,⁸ Bell⁹⁻¹¹ and Ikeda¹² have described the x-ray findings. These included varying degrees of irregular narrowing of the lumen of the large bowel. The cecum, which is the most frequent site of positive roentgenologic findings, is characterized by irregularity and deformity. An unusual degree of incompetence of the ileocecal valve, with rapid reflux of barium into the ileum, has been noted. The abnormalities suggest the findings in the ordinary type of chronic ulcerative colitis, aside from the changes of the cecum. There is a tendency, however, for the involvement to be less uniform and for abnormal segments of the bowel to be separated by what appears to be normal bowel. The wall of the large bowel is also relatively pliant and freely movable. The entire roentgenologic aspect of the disease is one of diminished intensity and severity

when compared with manifestations of other types of chronic ulcerative colitis. Amebic granulomas have also been described. There are irregular filling defects in the bowel very similar to carcinoma.

The incidence of positive roentgenologic findings in amebic dysentery varies considerably. Browne et al.,⁶ reporting on the findings in 141 cases in which barium-enema roentgenologic studies were done, showed a 36 per cent positive roentgenologic change. Edson and his associates,¹³ in a series of 20 cases, reported positive roentgenologic findings by barium enema in 80 per cent. Reeves, of Duke University, working with Ruffin of the same institute, in a series of 54 cases with *E. histolytica* in the stool, examined 19 patients by roentgenogram, and abnormalities considered to be indicative of amebi-

TABLE 3 Location and Form of *E. histolytica* in 60 Cases of Amebiasis

RESULT OF EXAMINATION	NO. OF CASES
Cysts found in stools	34
Motile trophozoites found in stools	5
Cysts found in proctoscopic specimen but not in stools	4
Trophozoites found in proctoscopic specimen but not in stools	3

asis were found in 68 per cent.¹¹ King, of Memphis, observed roentgenologic abnormalities in the large bowel of all 12 cases of amebic dysentery in which examinations were done.¹⁴ In 3 of these cases, x-ray evidence first suggested the possibility of amebic dysentery, and this was later confirmed. In our group examinations on 28 patients revealed that 32 per cent had roentgenologic changes resulting from the amebic infestation of the large bowel. All cases with positive findings had repeated x-ray examinations after therapy, and in each case the findings returned to normal.

In our series there were 6 patients who were considered to have amebic hepatitis and 1 who had an amebic liver abscess. All these patients complained of pain in the region of the liver that varied from rather sharp and severe to dull and aching. Patients usually complained of pain in the region of the right costal margin, most frequently in the anterior or axillary region and at times posteriorly as well. In 1 case of liver abscess, the complaints and physical findings concentrated interest in the right lower pulmonary area. In 6 of the 7 cases there were acute temperature rises, which were intermittent in type and reached 103 to 104°F. Chills were present in 3 cases. Jaundice was observed clinically in 2 and in 1 was subclinical, the icteric index being 12.6. There was marked weight loss in 6 cases, varying between 10 and 35 pounds. Diarrhea was present in 4 cases on admission. One patient had no diarrhea on admission, but had had a positive history previously. The stools were bloody in 2 cases. The most important clinical

findings were hepatomegaly and marked tenderness over the liver. In 3 cases the liver could not be palpated because of extreme tenderness and rigidity. The spleen was palpable in 2 patients, both of whom had a history of malaria. The total white-cell count was elevated in all but 1 patient. The counts varied from 11,000 to 26,000, with a predominance of neutrophils. One case showed no elevation of white-cell count and no fever, but followed the low-grade symptomatic picture described by Castellani¹⁴ and Hurst¹⁵ and recently classified by Klatskin¹⁶ as chronic hepatitis.

Stool examination showed trophozoites and cysts in 2 cases. In the remaining 5 the stools were normal. Proctoscopic examinations in three cases with negative stools disclosed no disease. Barium enemas were done in 2 cases but were negative. In 2 others complement-fixation tests for *E. histolytica* were positive. Neither of these patients had positive stools, and proctoscopic examination was negative in both. Liver-function tests in 1 case were normal. X-ray films of the chest were done in 4 cases. In 1 there was elevation of the diaphragm. In another a circular demarcated area of density in the posterior portion of the right lower lobe obscured the posterior sulcus and posterior half of the diaphragm.

There is little doubt that emetine is the drug of choice in amebic infestations of the liver. The response to emetine in cases of amebic hepatitis is quite dramatic. The amount used is generally between 0.4 and 0.8 gm. given parenterally in doses of 0.06 gm. daily. When 0.8 gm. is used it is wise to allow a short rest period after the seventh dose. Emetine in sufficient dosage is also the drug of choice in amebic liver abscesses, in which the amount needed is usually much larger. Most of the patients with amebic abscesses previously reported cured with emetine alone received between 0.6 and 0.8 gm. Klatskin¹⁶ recently reported using the equivalent of 1.3 gm. of emetine in 7 cases of the early, acute type. This type of case responds better, generally, than the chronic abscesses. Payne¹⁷ has recently reported, however, the successful use of emetine alone in large chronic abscesses. His 24 cases required an average of 2.4 gm. given over a period of one hundred and eight days. In 1 case he used 4 gm. in one hundred and twenty days.

The indications for aspiration are failure of the patient to show any improvement after 0.8 gm. of emetine and evidence that an abscess near the surface is getting larger under emetine therapy.

The indications for surgical drainage are rupture of an abscess into a serous cavity with the exception of rupture into the pleural cavity, when aspiration in addition to emetine may suffice, superficial abscesses located in the left lobe of the liver, and secondary bacterial infection of the abscess. In bacterial infection, which is an infrequent com-

plication, the use of aspiration, emetine and chemotherapy may eliminate the necessity of operation.

It is also believed that all cases of amebic hepatitis and abscess should be treated with one of the iodine-containing oxyquinolines. This is given usually after the course of emetine. Carbarsone, being an arsenic preparation, has been considered to be contraindicated in amebic liver involvement. This opinion, however, has been questioned.¹⁸

The treatment of acute or chronic amebic dysentery consists in the use of the following drugs in various combinations: emetine, carbarsone, chiniofon, Diodoquin and Vioform. There is considerable difference of opinion regarding which of these should be used and in what combinations. It is the belief of the majority that emetine administered parenterally, in addition to one or more of the enteric drugs, should be employed. D'Antoni,¹⁹ however, has advocated the use of Diodoquin in doses of 0.63 gm. three times a day for twenty days, without emetine, and has reported 95 per cent cures.

The schedule used at this hospital consisted of 0.06 gm. of emetine daily for six days, 0.75 gm. of carbarsone being given concurrently each day for a week, followed by 1.8 gm. of Diodoquin daily for two weeks. We have also used Diodoquin as advocated by D'Antoni. The effect on the symptoms and laboratory findings was similar in both groups. Rarely were chiniofon or carbarsone enemas administered. We have not used chiniofon extensively, since it often produced rectal burning and severe diarrhea.

Recently, Lewis²⁰ has advocated emetine parenterally, as well as Vioform orally and in retention enemas in cases of acute and chronic amebic dysentery. The results of this regime in refractory cases have been excellent.

It is our opinion that the immediate results regarding symptoms and laboratory findings will be good in the majority of cases, whatever regime is used. In the refractory cases one may be forced to resort to many types of regimes to obtain good results.

We were unable to carry out any long-range studies on our patients, so that no attempt was made to determine the percentage of relapses. Just which type of treatment will result in the least number of relapses remains to be seen. Amebiasis is a disease in which treatment is difficult to evaluate, and it is often impossible to differentiate reinfections and relapses.

It is well to mention the toxic effects of emetine. There have been reports of death following therapy.²¹ The toxic action is chiefly on cardiac and striated muscles. The patient receiving emetine should be on bed rest and should be examined each day by a physician, attention to any irregularity of pulse, soreness of muscles and fall of blood pressure being noted. If available, electrocardiograms should be taken before and during the course of treatment.

When doses of 0.42 gm. or less are used toxic effects are rare. When larger doses are contemplated, it is well to allow sufficient rest periods between courses.

DISCUSSION

The diagnosis of amebiasis often requires extensive study. In many cases routine examinations of stools will reveal the presence of *E. histolytica* as the causative agent. In others, the correct diagnosis may be arrived at only by proctoscopic examination. The appearance of the rectosigmoid mucosa is often quite typical of amebic dysentery. In other cases, the disease is difficult to distinguish from ulcerative colitis due to chronic bacillary infection or that due to idiopathic ulcerative colitis. Scrapings of the ulcers should therefore be done, and the material examined both for the presence of motile trophozoites and cysts of *E. histolytica* in all cases, regardless of the appearance of the rectosigmoid mucosa.

X-ray examination of the large intestine often offers valuable information and may be the first clue that the patient has amebiasis. It also serves to eliminate other diseases, such as carcinoma, and thus has a twofold purpose. We have already described the roentgenologic findings in amebic infestation of the large bowel. Differentiation between amebic granuloma of the large bowel and carcinoma is often difficult. In some cases resections of portions of the bowel have been done with a preoperative diagnosis of malignant tumor, and the specimen has shown amebic granuloma of the bowel.²³⁻²⁴ It is well to remember that carcinoma may also occur in patients with amebiasis. Reed and Anderson²⁵ have reported 4 cases with a long history of amebiasis and with lesions of the colon that were thought to be amebic and later turned out to be carcinoma.

Roentgen-ray differentiation of amebic granuloma and carcinoma of the large intestine has been emphasized by Bell,⁹⁻¹¹ who points out that the presence of associated abnormal findings in the cecum favors the diagnosis of amebiasis. When such findings are lacking, a therapeutic test is considered to be indicated if there is any associated clinical or laboratory evidence of amebiasis. Symptoms due to amebiasis show improvement after two weeks of antiamebic therapy.

The value of x-ray and fluoroscopic examination of the chest in cases with liver involvement with and without extension into the lung and pleura has been emphasized by Ochsner and DeBakey²⁶ and by Sodeman and Lewis.²⁷

Demonstration of the etiologic agent in any disease places therapy on solid ground. The finding of cysts and trophozoites of *E. histolytica* depends on many factors: the ability of the examiner to recognize the presence of trophozoites and cysts in the stools, the number of stools examined and the type of examination. The examination of the

stools should be made as soon as possible after they are passed, since the trophozoites often die and disintegrate in the stools a short time after they are passed. Cysts should be searched for both by the iodine-stained or hematoxylin-stained films and by the zinc sulfate centrifugal flotation method. The study of purge as well as routine stools is of value. The value of scrapings of the rectosigmoid mucosa has already been emphasized. Nevertheless, a certain percentage of patients with amebiasis will not show either trophozoites or cysts. Sawitz and Faust²⁸ state that the ameba can be detected with the use of iodine-stained or hematoxylin-stained film, in combination with the zinc sulfate centrifugal flotation method, if five stools are examined, in between 70 and 90 per cent of cases. In our series the etiologic agent was demonstrated in 77 per cent of cases.

Sodeman and Lewis²⁷ have ably discussed the differential diagnosis and the importance of making an early diagnosis of amebic hepatitis. They were able to demonstrate *E. histolytica* in the stools of 55 per cent of cases of amebic hepatitis and 29 per cent of cases of amebic liver abscess. In our group of 7 cases we were able to demonstrate the causative organism in 2 (29 per cent). In 2 other cases with liver involvement, complement-fixation tests for amebiasis were positive. In both cases treatment was instituted before the results of the tests were obtained. Tests were done at the Army Medical School, Washington, D. C., and it took a few weeks for results to be returned. The complement-fixation test, no doubt, would be of value in cases suspected of amebiasis in which no definite ameba can be found, but as yet this test is not in common usage. We are in complete agreement with Sodeman and Lewis that the diagnosis of amebic hepatitis should be made on a clinical basis alone, even when laboratory examination fails to disclose the causative agent, which should nevertheless be sought for diligently.

D'Antonio²⁹ has subdivided amebiasis into the following clinical groups: asymptomatic, and symptomatic, including asymptomatic and syndromic amebiasis, dysentery (acute or chronic), hepatitis and liver abscesses and involvement of other organs (abscesses of lung, brain and so forth).

We have not attempted to subdivide our cases into these classifications. No cases of asymptomatic carriers were included in our series. It has been our experience that the others often merge. A chronic case may suddenly show acute symptoms; in others, falling into the so-called "asymptomatic" or "syndromic" group, the patient may have had dysentery in the past or may develop it in the future. We have listed our findings in patients with liver involvement, and also in 1 with liver involvement and secondary pulmonary involvement. One patient in the series showed a perianal fistula, which appeared at the time of the acute

dysenteric symptoms. We have not seen involvement of other organs.

In our group of patients 53 were from New England. When one considers that this is only one Army installation, that many cases with mild symptomatology are not detected, that many others may have been in symptom-free remissions since discharge from the Army and that the incubation period of the disease may be quite long, it is logical to assume that amebiasis is not unusual in New England. Of our group, 22 patients had received treatment prior to admission to the hospital and had relief of symptoms and yet had recurrences for which they were again hospitalized. This is not to subscribe to a common adage "Once amebiasis, always amebiasis," but merely to emphasize that the disease recurs. There is a variance of opinion regarding the frequency of recurrence. Mateer,³⁰ using a single standard ten-day course of carbarsone and chimofof enemas, reported cure in 97 per cent of 104 patients followed from six months to three and a half years. On the other hand, Lamb and Royston,³¹ employing even more intensive therapy with chronic relapsing cases with a history of five months' to five years' duration, found that 91 per cent followed for nine weeks had relapses. It is not the purpose of this paper to discuss the question of recurrences but merely to state that, in our observations, relapses have been quite frequent.

In a certain group of patients with dysentery due to *E. histolytica* no positive findings may be elicited by stool, proctoscopic or x-ray examination. These cases present a difficult diagnostic problem and are often labeled irritable colon, mucous colitis and so forth. In such cases the history often gives the clue. Patients with psychogenic disturbances resulting in diarrhea often have a much older history, and psychogenic causes can often be demonstrated. We also believe that any person who has previously had amebic dysentery, who complains of diarrhea and in whom no known cause for the diarrhea can be demonstrated should be considered as potentially having amebic dysentery and treated accordingly. This policy could also apply to patients without a specific history of amebic infestation who have been in a highly endemic area and in whom likewise no cause for diarrhea can be found. It has been gratifying to see a number of such cases completely clear up under therapy. It is realized that patients with psychogenic disturbances of the bowel have been located in endemic areas and that the symptoms are not due to amebic infestation. In these cases, however, one can generally obtain a definite psychogenic background, and little is lost even though therapy may be given with complete failure.

We should also like to stress the similarity of the appearance of the rectosigmoid mucosa on proctoscopic examination in amebic dysentery and that

seen in both bacillary dysenteries and idiopathic ulcerative colitis. Attention has been called to the fiery-red mucosa of acute bacillary infections and the discrete, undermined ulcers of typical amebic dysentery. In the more chronic stages of amebic dysentery and bacillary infections, mixed secondary infestation with the colon bacillus, staphylococcus and streptococcus may so alter the appearance of the mucosa that its specificity is lost and the appearance is indistinguishable from that of typical ulcerative colitis. We therefore believe that if there is a definite history of amebic infection and if stool cultures and examination fail to show a specific etiologic agent, antiamebic therapy is indicated, even though the appearance of the rectosigmoid mucosa suggests idiopathic ulcerative colitis. We have seen 2 cases diagnosed as idiopathic ulcerative colitis in which the patients, who were given symptomatic treatment for six months without relief, showed complete clearing of symptoms and return of the rectosigmoid mucosa to normal when placed on antiamebic therapy.

SUMMARY

Because of the great number of men and women of the armed forces who have lived in areas highly endemic for amebiasis and who now have returned to civilian life, amebiasis will probably be more frequently encountered in post-war civilian practice in New England.

The clinical picture, laboratory findings, proctoscopic findings and roentgen-ray manifestations in 60 cases of amebiasis are reviewed. The diagnosis of amebiasis often requires extensive study, including repeated stool, proctoscopic and x-ray examinations.

The liver is not too infrequently involved in amebiasis, and the etiologic agent cannot be demonstrated in a large percentage of cases.

The proctoscopic visualization of the rectosigmoid mucosa in chronic amebic dysentery may be indistinguishable from that of idiopathic ulcerative colitis.

The similarity of amebic dysentery to functional disturbances, frequently described as "irritable colon," "mucous colitis" and so forth, is discussed. Patients presenting such a symptom complex, who have had a previous history of amebic dysentery or have lived in an area highly endemic for *Endamoeba histolytica* should be given a trial of antiamebic therapy.

ATYPICAL ADDISON'S DISEASE ASSOCIATED WITH DIABETES MELLITUS*

Report of a Case

DANIEL K. ADLER, M.D.†

SYRACUSE, NEW YORK

SINCE the description of the syndrome of adrenal cortical insufficiency by Addison in 1855, a review of the literature reveals only 16 accepted cases in which this syndrome appeared in combination with diabetes mellitus. Nearly seventy-five years elapsed after Addison's paper before a case showing this combination was reported by Unverricht¹ in 1926. It has since been recognized that these cases fall into three distinct groups, depending on the time of development of one disease in relation to the other. Thus, there are 4 cases in which, as nearly as could be determined, the two diseases developed simultaneously, 3 cases in which patients with Addison's disease subsequently developed diabetes mellitus and 9 cases in which Addison's disease followed the onset of diabetes mellitus (Table I).

The following case, in which the diabetes was present for at least two years before the Addison's disease made itself apparent, is reported not only as an additional case of this rare combination of two metabolic diseases but also because of the markedly atypical character of the picture of adrenal cortical insufficiency as it affected the patient.

K. M., a 20-year-old Irish girl, was first admitted to the hospital on November 1, 1944, in severe diabetic acidosis. The past history was essentially irrelevant until 4 months before admission when she noted the sudden onset of polyuria, polyphagia, polydipsia, weakness and weight loss. A physician made a diagnosis of diabetes mellitus, gave her a dose of insulin and placed her on a restricted carbohydrate diet, with instructions to return in 1 week. Because she felt somewhat better and did not want to stop work, however, she did not return. Five days prior to admission she failed to observe her diet because she felt very hungry. Two days later she developed a sore mouth, nausea, vomiting and dizziness. On the day of admission she was seen by her doctor because of progression of these symptoms. He administered 35 units of protamine-zinc insulin and 30 units of regular insulin and sent her to the hospital.

Physical examination revealed an acutely ill, dehydrated and lethargic young woman whose mouth contained scattered necrotic lesions involving the gingiva as well as other mucosal areas. The chest was clear and the heart was normal. The skin was dry and warm and somewhat loose. The rest of the physical examination was negative.

The blood pressure was 115/65 and the pulse was of good quality.

The urine showed a + + + + test for sugar, a + + + + test for acetone and a + + test for diacetic acid. The blood sugar was 360 mg. per 100 cc., and the carbon dioxide combining power 32.1 vol. per cent.

A diagnosis of diabetes mellitus and diabetic ketosis was made and the patient was started on treatment with continuous intravenous fluids and insulin. During the following 20 hours she received a total of 390 units of regular insulin and 5660 cc. of 5 per cent glucose in physiologic saline solution at which time the blood sugar had fallen to 130 mg. per 100 cc. and the carbon dioxide combining power had risen to 48 vol. per cent. The urine showed a + test for sugar with no acetone or diacetic acid. By that time the oral condition had become much worse and the temperature

*From the Second Medical Service, Mount Sinai Hospital.

†Formerly assistant resident in medicine, Second Medical Service, Mount Sinai Hospital.

had risen to 101°F She was placed on sulfadiazine for 2 days, followed by 4 days of penicillin, with good results Meanwhile, an attempt was made to regulate the diabetes with the use of protamine-zinc insulin She was placed on a daily diet of 250 gm of carbohydrate, 90 gm of protein and 80 gm of fat (2080 calories), and on this diet she required 70 units of protamine-zinc insulin to regulate her sufficiently well for discharge It was on this regime that the patient was referred to the diabetic clinic for further care.

For the next 2 years the patient attended the diabetic clinic but was irregular in her appearances and was consequently difficult to control At various periods the insulin dosage had varied from 40 to 70 units of protamine-zinc insulin She had no further episodes of acidosis, but the urine frequently showed a ++++ test for sugar She admitted dietary excesses and apparently had no insight

the injection the patient became conscious Shortly thereafter the urine was again tested and again found to be free of sugar and acetone Because she still appeared somewhat lethargic, another 25 gm of glucose was given intravenously, after which she was taken to the ward, where the urine was again examined and showed a ++++ test for sugar with no acetone. She was quiet and still lethargic but was able to answer questions rationally, after a short delay

Examination of the blood on the next morning revealed a hemoglobin of 68 per cent and a white-cell count of 7700, with a normal differential The blood sugar was 215 mg, the cholesterol 215 mg and the urea nitrogen 18 mg per 100 cc The sedimentation rate was 42 mm (Westergren) in 1 hour

The temperature was 101°F, and the patient had no specific complaints except for marked weakness and lassitude

*Modified from Soffer³

whatever into her condition Three weeks before the second admission she was given 100 units of protamine-zinc insulin, but during the succeeding week she had four episodes of mild hypoglycemic shock on successive mornings Two weeks before admission she was placed on 25 units of protamine-zinc insulin combined with 50 units of regular insulin each morning and had no further episodes of hypoglycemic shock She stated, however, that for several mornings she had been feeling weak, dizzy and tired

On the morning of October 31, 1946, the patient awakened feeling weak, dizzy and nauseated She was aroused with some difficulty but was unable to eat her breakfast She was given a glass of orange juice and the regular morning dose of 50 units of regular and 25 units of protamine-zinc insulin Shortly thereafter she became much more drowsy and lethargic, whereupon her physician was called Under the impression that this represented impending diabetic coma she was given 30 units of regular insulin, after which she became unconscious and totally unresponsive to stimulation and was immediately sent into the hospital

Physical examination revealed an acutely ill young woman who was completely unresponsive The pharynx was slightly inflamed, and the lips were dry, with crusted sores at the corners The tongue was moist. The eyeballs were normal in consistence The lungs were clear The apical impulse could not be felt, but there was no cardiac enlargement to percussion The heart sounds were of good quality The pulmonary second sound was greater than the aortic second sound Sinus tachycardia at a rate of 140 per minute was present Examination of the abdomen was negative The skin was cool and dry There was no pigmentation of the skin or mucous membranes, and there were no dark freckles The deep reflexes were hypoaactive

The pulse was small and easily compressible The blood pressure was 90/54

When seen in the emergency room the patient seemed to be suffering from insulin shock This impression was further borne out by a urine examination, which showed no sugar and no acetone She was then given 50 cc of 50 per cent glucose in distilled water intravenously, without dramatic improvement. This therapy was repeated, and directly after

The blood pressure was 98/60, and physical examination was otherwise entirely negative. She was given no insulin, and the urine was examined at regular intervals During the latter part of the day she appeared very drowsy but did not sleep She refused to eat more than small amounts at any of her meals A blood culture was taken in an attempt to explain the fever, but this was later reported to have been negative An x-ray film of the chest showed normal lung fields and a small heart.

On the next day, the patient appeared even more drowsy and refused everything by mouth except small sips of water An afternoon urine specimen showed no sugar but gave a ++++ test for acetone, whereupon she was given 5 per cent glucose in physiologic saline solution alternated with physiologic saline solution parenterally The urine rapidly became acetone free, and the patient became more alert and responsive After 1600 cc of fluids had been administered the intravenous drip was discontinued On November 3 she ate much better, and the fractional urine specimens showed a ++++ test for sugar, on each occasion, with no acetone. The rectal temperature was somewhat lower but still ranged between 99 and 100°F Physical examination was again essentially negative She had been placed on a regular diet and on November 4 was started on 10 units of regular insulin each morning On that day the urine specimens taken at 8 and 11 o'clock showed a +++ test for sugar, with no acetone, and she was given an additional 20 units of regular insulin at 11 30 a m At 3 p m, while in the dentist's chair, she suddenly went into a shock-like state and was taken to the ward, where she was seen by an intern and found to be unresponsive, even to painful stimuli The pupillary reflexes were active, and the extremities were cold and moist. The pulse was regular at about 80 per minute Blood was drawn for a sugar determination, which was later reported to be 175 mg per 100 cc, and 25 gm of glucose was injected intravenously The patient responded rapidly, becoming awake and oriented within a few moments A urine specimen at that time showed a + test for glucose and no acetone After this episode she remained apparently quite well for the next four days On a regular hospital diet with 10 units of regular insulin daily the urine persistently showed a ++ to +++

test for sugar. A repeated sedimentation rate was reported as 61 mm. (Westergren) in 1 hour, and the fasting blood sugar was 195 mg. per 100 cc. The temperature ranged between 99 and 100°F. Agglutination tests for typhoid and Salmonella organisms were reported as negative. On November 8 the patient again felt listless and weak and vomited her breakfast. An intravenous infusion was started, and she received 1200 cc. of 5 per cent glucose in isotonic saline solution. During the infusion the symptoms disappeared and she felt much better, retaining the noon and evening meals. The urine during the day was acetone-free and gave a +++ to ++++ test for sugar. On the next morning she again awakened feeling listless and nauseated. After she had vomited her breakfast another intravenous infusion was started, 5 per cent glucose in isotonic saline solution being used. This was allowed to run for approximately 36 hours, during which the symptoms disappeared and she was again able to eat well and retain all her meals.

It was apparent that this was not an ordinary case of diabetes mellitus. The blood pressure was persistently obtained at a level of 90/54 or less. At the same time the radial pulses were hardly palpable. These factors, in addition to weakness and gastrointestinal disturbance, suggested the possibility of adrenal cortical insufficiency complicating the diabetes. Further questioning of the patient revealed that for the preceding year she had become more aware of increasing weakness and gradual loss of weight. She stated that prior to the present admission the weight had been 116 pounds. On November 11 the weight was 103 pounds. Another factor suggesting the diagnosis of Addison's disease was the rapid improvement in the lethargy and nausea and vomiting following the intravenous administration of glucose and saline solution. With this diagnosis in mind blood was drawn for serum sodium determination, a plain film of the abdomen was taken, and she was tested with tuberculin. The film did not reveal adrenal calcification and the intradermal tuberculin tests were negative up to a 1:100 dilution. Meanwhile, the patient had been changed from regular insulin to 30 units of protamine-zinc insulin each morning with a subsequent diminution in the urinary sugar excretion and with no untoward effects. The low-grade elevation of temperature persisted, as did the elevated sedimentation rate. X-ray films showed minimal thickening of the lining membrane of the right maxillary sinus.

After discontinuance of the intravenous infusion on November 11 the patient did well. She was ambulatory, ate well and appeared cheerful. The urine specimens continued to show sugar although she was on 30 units of protamine zinc insulin daily. On November 16 she again began to complain of nausea, vomiting, weakness, lethargy and severe abdominal pain limited to the epigastric region, without radiation. A hypodermoclysis of 5 per cent glucose in isotonic saline solution was started, but the symptoms persisted. The urine was free of acetone and gave a +++ to ++++ test for sugar on repeated testing. Physical examination revealed the blood pressure to be 68/50 and the pulse to be extremely weak. The lungs were clear and the abdomen was soft and nontender to palpation with no areas of spasticity. On November 18 the hypodermoclysis was removed and an intravenous infusion of 5 per cent glucose in isotonic saline solution was started. In addition she was given 5 mg. of desoxycorticosterone acetate hypodermically twice daily. The clinical response was rapid and dramatic. By the next morning she was no longer nauseated and felt stronger. She ate small amounts of food and the epigastric pain had disappeared. After 2 days of desoxycorticosterone acetate and intravenous therapy she was asymptomatic, and the blood pressure had risen to 100/60. At that time the blood sodium, as determined from a specimen drawn on November 15 was reported as 120.7 milliequivalents per liter, which appeared to confirm the diagnosis. Because of a lack of pigmentation, however, it was decided to establish the diagnosis more firmly. To this end the patient was treated with 6 gm. of supplementary salt in addition to 4 mg. of desoxycorticosterone acetate daily for a period of 11 days, at the end of which the blood sodium was 139.6 milliequivalents per liter — a value well within the normal range. The hematocrit reading was 29 per cent and the serum chloride was 104 milliequivalents per liter. With these values as a base line the desoxycorticosterone acetate was discontinued, and the patient was given a salt deprivation test, after the kidney function as determined by the urine concentration test and the phenolsulfonphthalein excretion test, had been shown to be normal. On December 1

she was placed on a diet containing 0.6 gm. of sodium a day. On the 7th day of this diet she began to complain of severe nausea and weakness. She appeared to be exhausted and to have lost weight. On the next day she was much worse and vomited several times. The blood pressure had fallen to 78/50, and it was found that she had lost 6 pounds during the course of the test. The hematocrit reading had risen to 41 per cent. The serum sodium had fallen to 127.6 milliequivalents and the serum chloride to 74.5 milliequivalents per liter. In spite of an intake of only 15 gm. of sodium chloride daily, the

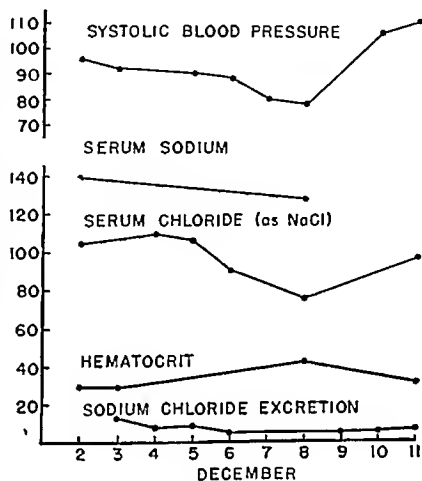

FIGURE 1

daily urinary output of sodium chloride was at no time below 4 gm. These changes are presented graphically in Figure 1.

Treatment with 5 mg. of desoxycorticosterone acetate intramuscularly was immediately started twice daily, with an intravenous infusion of 5 per cent glucose in physiologic saline solution. The response was again dramatic, with rapid disappearance of the symptoms by the next day. The blood pressure rose to 110/55, and the patient began gaining weight, was able to eat and rapidly regained strength and vigor. From then until discharge on December 22, she was symptom free and felt better than she had at any time during the previous year. The protamine-zinc insulin was gradually increased until she was receiving 45 units daily with no deleterious effects and the urine still contained about 10 to 15 per cent of sugar each day. The dosage of desoxycorticosterone acetate was slowly reduced to 1 mg. intramuscularly daily and the supplementary salt intake was maintained at 6 gm. on this routine she was discharged and referred to the diabetic clinic for continued observation.

DISCUSSION

The salt-deprivation test used in this case was described by Harrop, Weinstein, Soffer and Trescher¹ in 1933. Soffer² states that the two findings that make the diagnosis of Addison's disease conclusive are an excess of urinary salt excretion over the intake and a fall in the level of the serum sodium. It was determined to keep the patient on this test diet until she showed some signs or symp-

toms of adrenal cortical insufficiency. She was carefully watched, with frequent determinations of the urinary sodium chloride output, the blood sodium chloride level, the serum sodium and the hematocrit. Blood-pressure readings were made twice daily, and the patient was kept at bed rest. It can be seen that on the basis of sodium chloride intake, it was not until the seventh day that she developed the typical signs and symptoms of adrenal cortical insufficiency.

The absence of pigmentation in this case was a markedly disturbing feature and cast doubt on the diagnosis of Addison's disease until definite proof had been obtained by the salt-deprivation test. Pigmentation is one of the most characteristic features of Addison's disease and is usually the sign that leads one first to suspect this disease. The amount of pigment deposited varies from patient to patient; some patients show only a few black freckles. Others report the appearance of many more freckles than they had previously. Rowntree and Snell¹⁰ found only 1 case of lack of pigmentation in their series of 108 patients with proved Addison's disease.

Another disturbing finding in this case was the fact that the diabetes was only slightly modified by the advent of the Addison's disease. In view of the relation of the adrenal cortex to carbohydrate metabolism, one would expect considerable modification in the diabetes, with a reduction of the hyperglycemia and glycosuria and a lowering of the insulin requirements. Unverricht's¹ case showed a lowering of the amount of insulin required daily from 40 units to 5 units; Rogoff's¹¹ case a decrease of from 48 to 60 units to 5 to 10 units; Bloomfield's¹² case a decrease from 40 units to 8 units; and Bickel's¹⁵ case a decrease from 50 units to 10 units daily. At the time the patient left the hospital, although she was receiving 45 units of protamine-zinc insulin daily, the urine specimens continued to show a ++ test for sugar, with a daily average excretion of 1 to 1.5 per cent of glucose. The 45 units represents only a slight lowering from the insulin requirements of the preceding two years, which averaged approximately 65 units daily.

In spite of these discrepancies, the diagnosis of Addison's disease appears definitely established on both clinical and laboratory grounds. The poor response to intravenous administration of glucose, given for the insulin shock at the time of admission, should perhaps be considered the first clue that this was not a clear and simple case of diabetes mellitus. Whereas ordinary patients with insulin shock respond rapidly and dramatically to the intravenous administration of glucose, this patient did not and was still somewhat lethargic and disoriented after she had received 75 gm of glucose by vein. This response is in keeping with the course of Addison's disease, since patients with adrenal cortical insuffi-

ciency are markedly sensitive to insulin and go into much deeper shock than ordinary diabetic patients given a similar overdose.

The possibility that this patient was suffering from a combination of diabetes mellitus and Addison's disease dawned on the clinicians when it was realized that the radial pulse was nearly palpable although the general condition was satisfactory. Then the combination of asthenia with a history of weight loss, hypotension and gastrointestinal disturbances manifested by nausea, vomiting and abdominal pain became significant. This, in association with the marked improvement that followed the administration of salt and desoxycorticosterone acetate, suffices to justify the diagnosis. When to this are added the low blood sodium and the typical response to the salt-deprivation test with the fall in the blood chlorides and serum sodium, the lowering of the blood pressure, the rise in the hematocrit and the continued daily loss of more sodium chloride in the urine than was being ingested, it appears that the diagnosis of Addison's disease was definitely established.

SUMMARY

A case of atypical Addison's disease associated with diabetes mellitus is reported, and the literature concerning this rare combination is briefly reviewed.

The significance of the salt-deprivation test in combination with the clinical and laboratory findings as evidence for the diagnosis is discussed.

FURTHER OBSERVATIONS ON THE OCCURRENCE OF STREPTOCOCCI OF GROUPS OTHER THAN A IN HUMAN INFECTION*

GEORGE E. FOLEY†

BOSTON

THE occurrence of streptococci of groups other than A is rare in upper respiratory infections such as scarlet fever, tonsillitis and septic sore throat. These streptococci, however, are frequently isolated from sporadic infections, including septic abortion (Harc,¹ 1937), puerperal fever (Fry,² 1938), meningitis (Rantz,³ 1942), urinary infections (Porch,⁴ 1941), subacute bacterial endocarditis (Wheeler and Foley,⁵ 1945) and miscellaneous conditions (Wheeler and Foley,⁶ 1943). The predominant role of Group A streptococci in the over-all pattern of streptococcal disease in man is not disputed. The intention of the present communication is to re-emphasize the potential significance of the streptococci of groups other than A, which are too frequently disregarded by the medical bacteriologist.

During the past two years the serologic groups (Lancefield,⁷ 1933) of streptococci isolated in 118 cases of miscellaneous infections occurring in children and adults have been classified. These cases represent but a small percentage of the total patients with streptococcal illnesses admitted to the various institutions from which the data for this study were collected. The sample is selected in that only cases thought likely to be nonrespiratory in origin were included, in view of the difficulties involved in assaying the significance of streptococci of groups other than A isolated from the upper respiratory passages.

Such organisms were isolated in 95 (80 per cent) of this series of 118 cases. Of these 95 strains, a total of 77 (81 per cent) belonged to groups B, C-G, D, E, F and K. Concentrated extracts of the remaining 18 strains, all alpha streptococci, did not precipitate with antisera for groups A-M. Fourteen of these unclassified strains were isolated in cases of subacute bacterial endocarditis.

Streptococci occurred as pure cultures in a total of 93 cases (79 per cent). Of the strains other than Group A, 72 (75 per cent) appeared as pure cultures in primary isolation (Table 1).

The streptococci most frequently encountered in this study were those of Group D. The frequency with which this group was isolated is due in part to the number of cases of urinary infection and subacute bacterial endocarditis included in the series. However, even if these 34 cases are omitted,

Group D is second only to Group A in frequency of occurrence.

Of the remaining 16 strains of Group D streptococci, 4 were isolated from patients with intra-abdominal abscesses, and 4 from patients with postoperative peritonitis. Group D streptococci occurred as pure cultures in 3 of the former and in 2 of the latter cases. The other 3 strains were isolated in combination with *Escherichia coli*. All 8 patients were adults.

The other 8 strains of Group D streptococci, with the exception of a strain isolated in a case of septic abortion, were recovered from children. It is of interest that in streptococcal septicemia, Group D organisms occurred with about the same frequency as Group A in these cases (Table 1).

Streptococci belonging to groups B, C-G, E, F and K were encountered in infections occurring in adults as well as children. The majority of strains occurred as pure cultures. Groups H, L and M were not encountered in this series.

The streptococci isolated from patients with subacute bacterial endocarditis deserve comment. There were 34 cases in this series. Group D streptococci were isolated from blood cultures in 19 (56 per cent) of these cases, Group K in 1 (3 per cent), and serologically unidentified strains in 14 (41 per cent). Of the last group, 6 strains (18 per cent) synthesized a polysaccharide in 5 per cent sucrose broth but not in 5 per cent raffinose broth, fermented inulin but not raffinose and otherwise seemed to fulfill the criteria for "*Streptococcus s b e*," as described by White⁸ (1944), Niven, Kizuta and White⁹ (1946) and White and Niven¹⁰ (1946). Of the remaining strains in this group, 5 (14 per cent) seemed to be "*Str. mitis*," and 3 (9 per cent) were "*Str. bovis*." None of the "*Str. bovis*" strains hydrolyzed arginine, and only 1 strain of "*Str. mitis*" attacked this amino acid. This latter strain could be differentiated from "*Str. s b e*" only by its inability to change the viscosity of 5 per cent sucrose broth and its failure to ferment inulin (Table 2).

As observed by Foley and Wheeler¹¹ in 1945, reaction on horse-blood agar, with the exception of Group A (Lancefield¹²) and Group N (Sherman, Smiley and Niven¹³), does not necessarily correlate with serologic group. Alpha and beta strains were found in groups B and E, whereas alpha and gamma strains were encountered in groups F and K. Strains belonging to Group D exhibited the greatest variation, alpha, beta and gamma reactions were

observed on primary isolation of streptococci belonging to this group. Also in this group successive strains isolated from the same patients or different colonies in a single primary culture frequently showed variable reactions on horse-blood agar. One strain belonging to Group C-G — streptococci that ordinarily produce soluble hemolysin (Todd,¹⁴

of cultures cannot be ascertained if only colonies giving a beta reaction on blood agar are studied. This probably accounts for the failure to isolate organisms of groups E, H and K from normal throats during a survey of streptococcus carriers, as reported recently by the Commission on Acute Respiratory Diseases¹⁶. In the present study, for

1934) — exhibited a gamma variant in primary culture (Table 3).
The etiologic relation of streptococci of groups other than A to disease in human beings admittedly is not so clear-cut as could be desired, since a specific immune response in the host has not yet

example, only 21 (25 per cent) of 82 strains classified into serologic groups other than A gave beta reactions on blood agar.
The frequent occurrence of these streptococci in suppurative or generalized infection is in marked contrast to their relatively low incidence in upper respiratory disease. The low carrier rate, together with the further observation that this carrier rate is not subject to the seasonal changes observed in that for Group A streptococci,¹⁷ suggests that the epidemiology of infection due to these organisms is different from that in disease caused by Group A

been demonstrated against them. Such streptococci, except for certain strains of Group C-G, do not produce erythrogenic or soluble toxin (Pomales-Lebrón,¹⁶ 1940), streptolysin or fibrinolysin,¹² as measured by the techniques in use today. However, their isolation, usually in pure culture from suppurative or generalized infection, seems to be indicative of their etiologic significance. Although the results reported here are based on single-colony fishings, except in cases in which the primary culture showed more than one type of colony, it is unlikely that streptococci of groups other than A could occur so frequently as commensals with Group A streptococci of the same blood-agar reaction.
It is evident from the results of the present study and those reported elsewhere¹¹ that the incidence of streptococci of groups other than A in a given series

streptococci. An epidemiologic grouping, such as that commonly seen in cases of infections due to Group A organisms, is a rare occurrence. The majority of infections caused by streptococci of groups other than A are probably endogenous in origin rather than the result of person-to-person transmissions, the immediate precipitating factor disposing to such infection residing in the host.

rather than the parasite.¹⁸ This is apparent in postoperative infection and in subacute bacterial endocarditis.

The occurrence of the infection with organisms of groups other than A, furthermore, indicates that the "pathogenicity" of the streptococcus is not entirely dependent on serologic characteristics and emphasizes the lack of knowledge concerning the fundamental mechanics of streptococcal infection.

SUMMARY

A classification of the streptococci isolated from 118 cases of miscellaneous suppurative or generalized streptococcal infections occurring in children and adults revealed that 95 (80 per cent) of these strains were of groups other than A. Strains belonging to groups D, B, K, C-G, F and E were encountered in that order of frequency, 72 (75 per cent) of these strains occurred as pure cultures on primary isolation. Serologically unclassified alpha streptococci were isolated from this series about as often as Group A strains.

The predominance of Group D streptococci can be accounted for in part by the number of cases of urinary infection and subacute bacterial endocarditis in the series. In 34 cases of the latter, Group D streptococci were isolated in 19 (56 per cent), Group K in 1 (3 per cent) and serologically unclassified alpha strains in 14 (41 per cent). Six of these serologically unclassified strains appeared to be "*Streptococcus s. b. e.*"

MEDICAL PROGRESS

PRACTICAL CONSIDERATIONS OF VENOUS PRESSURE (Concluded)*

HUGH HUDSON HUSSEY, M.D.,† AND HAROLD JEGHERS, M.D.‡

WASHINGTON, D. C.

DIAGNOSTIC VALUE OF REGIONAL DIFFERENCES IN VENOUS PRESSURE

In the older literature on venous pressure almost the entire interest centered on values obtained by determination of the venous pressure in one arm. In recent years, it has been demonstrated that comparison of pressure in various peripheral tributaries of the inferior and superior vena cavae greatly increases the diagnostic value of venous-pressure measurements for certain types of disease. Although the literature on the diagnostic significance of regional differences in venous pressure is somewhat limited, the value of this technic is strongly indicated by those who have used it. One can predict that this approach to the use of venous-pressure determinations will find an increasing scope of usefulness. Table 1 presents a list of diagnostic possibilities for a variety of possible regional venous-pressure determinations. Each of these is discussed in further detail in the following sections. Reference is not made to the technic of measurement of intra-atrial pressure by venous catheterization of the right side of the heart.

Diminished Pressure in All Peripheral Veins

It is well known that in shock (peripheral circulatory failure) the systemic venous pressure is characteristically depressed.⁶ Venous-pressure determinations are not ordinarily required for the diagnosis of shock. In fact, the diminished pressure and collapsed state of the veins in this condition frequently make it difficult to insert a needle for venipuncture to obtain blood. Venous pressure in shock may be as low as 10 to 20 mm of water.⁴⁸ Gunther⁴⁹ and Henstell and Gunther⁵⁰ have shown that in cases of shock there is a lowering of intramuscular and venous pressure before the values for plasma volume and arterial blood pressure are altered. When a venous-pressure apparatus is not available one can follow Fishberg's⁴⁸ suggestion and note the poor filling of the superficial veins of the upper extremity when the hand is held below the level of the

heart. This clinical observation will suffice to indicate that the venous pressure is low. One would expect the venous pressure to be low in ordinary syncope as well.

Slight temporary depressions in venous-pressure levels may occur normally in a number of procedures. Abdominal compression in the normal supine subject may produce a fall in average arm-vein pressure equivalent to 17 mm of water,² normally, the venous pressure falls during the Müller experiment³, and hyperventilation produces some fall in venous pressure. Such minor and temporary depressions, which are of no clinical importance, are occasionally noted, and therefore their significance should not be misunderstood.

Elevated Pressure in All Peripheral Veins

The most extensive use of venous-pressure measurements has been made in the study of congestive heart failure. The literature abounds with reports that attest to the value of the procedure in this connection.¹⁻⁷ In the past few years a number of studies^{36, 51-56} have led to uncertainty regarding the manner in which elevation of venous pressure results and its place in the mechanism of heart failure. This uncertainty about sequence and mechanism does not detract from the practical value of the test.

In failure of the right ventricle alone and in general cardiac failure there is a comparable elevation of pressure in all the systemic veins. Isolated failure of the left ventricle does not influence the venous pressure.^{4, 7} At times, when a patient with right ventricular failure improves rapidly with treatment, disappearance of edema and hepatomegaly may lag behind the return of the venous pressure to a normal level.^{3, 4} For example, intravenous administration of certain drugs, including aminophylline, mercurial diuretics and digitalis, is known to bring the elevated venous pressure down rapidly. This may be confusing if earlier measurements have not been obtained. Also, in cases of mild heart failure the venous pressure at rest may be persistently normal.³ Often, confusion can then be dispelled by careful use of the maneuver for demonstration of the hepatojugular reflux previously mentioned. Cases of persisting right ventricular failure in which determination of venous pressure, including abdominal compression, is entirely normal must be rare. In their recent review

with inferior-vena-cava blood flow Brams, Katz and Kohn⁶⁴ have demonstrated that distention of the abdominal cavity of a dog with air can elevate the iliac venous pressure to a level equivalent to 620 mm of saline solution. Their experiments suggest that artificial pneumoperitoneum in human beings and the so-called "spontaneous valvular pneumoperitoneum,"⁶⁵ which results from rupture of an air-containing viscus, could likewise impede blood flow in the inferior vena cava sufficiently to elevate the venous pressure in the leg.

During pregnancy local disturbances in the venous circulation of the lower extremities are quite common, as manifested by the development of varicose veins or the aggravation of varicosities already present, by the appearance of edema in which cardiac, renal, nutritional or endocrine causes are obviously lacking, and by the occurrence of acute thrombophlebitis, usually as a post-partum complication.⁶⁶ Studies initiated by Burwell⁶⁷ and confirmed by others^{68, 69} agree that, although the antecubital venous pressure in normal pregnancy is not significantly different from that in the non-pregnant state, the femoral venous pressure is increased in the latter part of pregnancy. McLennan,⁶⁸ in a detailed investigation of 255 pregnant women, made the following observation:

Femoral venous pressure begins to rise in the early part of the second trimester, rises rather rapidly between the twentieth and thirtieth weeks of gestation, then somewhat more slowly to reach an average peak value at term of approximately 240 mm of water. It falls quickly after delivery to nonpregnant levels and apparently lies somewhat below the average control level during the puerperal period of bed rest.

This regional difference in venous pressures is believed to be responsible for the venous collateral patterns that frequently develop during pregnancy.⁶⁷ Veal and Hussey⁶⁶ regard the elevated femoral venous pressure in pregnant women as contributing to the formation of edema of the lower extremities and the incidence of varicose veins in pregnancy as being directly related to the venous pressure in the legs. The major factor responsible for the elevated leg venous pressure is obstruction to venous outflow by the gravid uterus,⁶⁶⁻⁶⁸ although Burwell⁶⁷ believes that inflow of a large amount of blood via the placenta may be an additional factor.

Nearly all types of malignant renal tumors are capable of invading the renal vein and inferior vena cava^{69, 70} and may produce obstruction of the inferior vena cava and even invade the heart. In the older literature obstruction of the inferior vena cava was suspected only when evidence of collateral circulation developed. As may be expected, a striking elevation of leg venous pressure occurs in such cases, and its measurement is warranted in the study of a renal tumor when the question of metastatic spread to the inferior vena cava arises. In a typical case Ferris and Blankenhorn⁶³ noted a leg venous pressure equivalent to 320 mm of water,

whereas the arm pressure was equivalent to only 70 mm. In a similar manner primary liver carcinoma may invade the inferior vena cava⁷¹ and produce obstruction to blood flow, with resultant increase in femoral-vein pressure.⁶³ Figures obtained in a representative case revealed a leg venous pressure equivalent to 220 mm and an arm venous pressure equivalent to 50 mm of water.⁶³

Ligation of the inferior vena cava as a means of preventing pulmonary embolism in the presence of phlebothrombosis of the leg or pelvic veins has become an accepted therapeutic procedure.⁷² One would naturally expect a striking elevation of leg venous pressure in such cases. In a detailed study of 5 patients after ligation of the inferior vena cava Burch and Winsor⁷³ noted pressures in the veins of the dorsum of the feet ranging from the equivalent of 170 to 506 mm of water, with normal antecubital-vein pressure. The venous pressure in the legs had not returned to normal as long as ten months post-operatively and was inversely related to the degree of development of the collateral circulation. In most cases edema of the feet persisted for many months.

Obstruction of the inferior vena cava from thrombosis, thrombophlebitis, pressure from adjacent masses and primary tumor of the inferior vena cava should act much as ligation of the vessel and should selectively elevate the venous pressure of the legs.^{63, 74-76} If the obstruction is of slow onset with involvement of the renal veins the resultant picture is one that closely resembles the nephrotic syndrome.⁷⁵ Tumors that metastasize to the inferior vena cava may eventually spread or be carried to the heart and may produce elevation of the venous pressure in the arms as well.

The inferior vena cava passes through the posterior portion of the liver in the right costovertebral sulcus. This close anatomic relation explains the fact that localized intrahepatic tumors may cause inferior-vena-cava obstruction with resultant increase in leg venous pressure. Venous pressures given in a representative case were equivalent to 180 mm of water in the legs and to 40 mm in the arms.⁶³ A comparable situation could exist for a single congenital cyst or an echinococcus cyst in the right lobe of the liver.

Ferris and Blankenhorn⁶³ have described a new sign, which is diagnostic of solitary abscess in the right lobe of the liver. In each of 5 consecutive cases of this lesion they noticed an elevation of pressure in the leg vein, that in the arm being normal. The leg pressures in these cases were equivalent to 140 to 370 mm of water, whereas the arm pressures varied from 40 to 80 mm. The leg pressure was noted to drop when pus was aspirated from a liver abscess. The authors postulate that an abscess mass may press not only on the inferior vena cava to raise the leg venous pressure but also on bile or portal radicles to cause obstructive jaundice or

signs of portal congestion. The specific value of the Ferns-Blankenhorn sign becomes clear with the demonstration that diseases causing a more or less symmetrical enlargement of the liver, such as fatty liver, portal cirrhosis, acute hepatitis and diffuse carcinomatosis, do not affect the femoral venous pressure, regardless of the size of the organ. Hepatomegaly due to cardiac failure increases both the leg and the arm venous pressures to a comparable degree. Therefore, a clinical picture characterized by infection, an enlarged liver and increased femoral venous pressure with normal ante-cubital venous pressure is strongly suggestive of a solitary abscess of the right lobe of the liver.

Subphrenic abscess on the right may also cause a specific elevation in the leg venous pressure.⁶⁴ The physical findings in this condition and roentgenologic studies of the chest and diaphragm should make possible its distinction from a solitary liver abscess.

It is well known that thrombosis in the femoral and iliac veins frequently follows certain types of abdominal operations, particularly those in the regions of the large veins. During standard abdominal operations in 10 cases Veal and Hussey⁶⁵ studied the effects of operative procedures on the pressures in the ante-cubital and saphenous veins. It was noted that operative manipulations within the abdominal cavity caused an immediate rise in pressure in the saphenous vein without directly affecting the ante-cubital pressure. These elevated saphenous-vein pressures fluctuated widely throughout the operation, were occasionally of great magnitude and generally returned to normal at the termination of the operation. In a somewhat similar study Davis, Gilman, and Freedberg⁶⁷ noted increases in pressure in the veins of the foot in the course of operations on the uterus and its adnexa, with less striking changes during cholecystectomy and inguinal herniorrhaphy. These authors discussed in some detail the possible role of local venospasm as a factor in the rise in venous pressure obtained in the course of certain operations. It is of interest that Davis et al.⁶⁷ observed that the severity and frequency of changes in pressure in the leg veins during abdominal hysterectomy, cholecystectomy and herniorrhaphy had about the same incidence as postoperative thrombosis and embolism in these operations — 4.1 per cent, 2.3 per cent and 1.3 per cent, respectively — as reported by Barker and his associates.⁶⁸

During the postoperative period tight abdominal or groin binders may elevate venous pressure in the legs, particularly if marked abdominal distention develops after the binder is applied.⁶⁹

Elevated Pressure in Arm Veins Alone

When the superior vena cava is obstructed and the inferior vena cava patent, the pressure in the ante-cubital veins is significantly higher than that in the femoral vein and shows an additional tempo-

rary increase with the exercise test mentioned above. The same effect may be expected when both innominate veins, both subclavian veins, or both axillary veins are obstructed, although examples of such bilateral venous occlusion must be rare. Katz et al.⁵⁰ have reported a case of bilateral innominate-vein thrombosis in which the clinical picture was indistinguishable from superior-vena-cava obstruction except by means of phlebography.

The principal causes of obstruction of the superior vena cava without involvement of the inferior vena cava (superior-vena-cava syndrome) are aneurysm of the arch of the aorta, bronchogenic carcinoma and mediastinal lymphoma.⁵¹ Less frequent causes are metastatic carcinoma of mediastinal lymph nodes, primary thrombosis and mediastinitis.⁵²

The completeness, duration and site of the obstruction of the superior vena cava influence the effects noted in the venous circulation. More or less complete obstruction, of course, produces a rather spectacular picture, and most of the reports in the literature are concerned with cases of this type. It has been shown, however, that minor degrees of obstruction also occur and are detectable mainly by venous-pressure measurement.⁵³ In a study of 35 cases representing the superior-vena-cava syndrome, there were 20 cases in which the venous pressure in the arm was equivalent to 300 mm of saline solution or more.⁵⁴ On the other hand, in 6 cases the venous pressure was equivalent to less than 200 mm and could be evaluated only by comparison with measurements of femoral-vein pressure, which were significantly lower. In the same study it was pointed out that there may also be a significant difference of venous pressure in the two arms as a result of involvement of one innominate vein as well as the superior vena cava.

With the passage of time, the venous pressure in the arms may go higher, on account of increasing obstruction to the superior vena cava.⁵⁵ Under appropriate circumstances such a change may represent an important indication for surgical exploration of the mediastinum. On the other hand, lowering of the venous pressure has been observed to result from development of collateral circulation, shrinkage of a mediastinal tumor by means of x-ray therapy, relief of complicating heart failure, mediastinal decompression⁵⁶ and release of the obstruction of the superior vena cava by severing a constricting band.⁵⁷

The site of obstruction of the superior vena cava is important chiefly with reference to the azygos vein. Obstruction above the point of entrance of this vein into the vena cava has less severe effects for the obvious reason that the azygos then serves as part of the collateral circulation. On the other hand, when this vein is also obstructed, blood from the superior-vena-cava system must return to the heart by way of the inferior vena cava. Under these

circumstances, it has been shown that venous flow and therefore venous pressure, in the tributaries of the superior vena cava, respond to certain maneuvers in a way that resembles the normal response in the tributaries of the inferior vena cava^{33, 43}. Thus, the venous pressure in the arms rises when the abdomen is compressed, and a paradoxical oscillation of venous pressure with respiration can be observed in the cervical veins and at times in the antecubital veins as well.

In the superior-vena-cava syndrome the increased volume of blood carried by the inferior vena cava as a collateral channel does not influence the pressure in the femoral veins⁴³. It remains normal (low by contrast) unless there is some additional factor obstructing flow in the inferior vena cava.

Pressure More Elevated in One Arm Than in the Other Combined with Lower or Normal Pressure in Leg Veins

When there is no cause for localized obstruction to flow in the veins of either upper extremity, it may be expected that venous-pressure measurements obtained simultaneously in both arms will not differ by more than the equivalent of 10 mm of saline solution²⁴. This is also found to be true in cases of heart failure, although the measurements, of course, are higher. Conditions that impede blood flow in the innominate, subclavian or axillary vein on one side without equal change on the other produce correspondingly greater differences in venous pressure in the two arms.

In order of frequency, the main local causes of obstruction of the axillary and subclavian veins are malignant neoplasm (usually intrathoracic), thrombosis secondary to heart failure and thrombosis secondary to trauma or effort of the arm and shoulder⁸⁴. The mechanism of venous obstruction by malignant tumors may be compression of the vein, filling of the lumen by invading tumor cells or thrombosis secondary to such invasion. Thrombosis accompanying heart failure has been reported only in severe cases and is thought to be the result mainly of stagnation of venous blood⁸⁴. The fact that it usually occurs on the left side has been explained by the greater immobility of the left arm in most bedridden cardiac patients and by the longer, more tortuous course of the left innominate vein. Traumatic or effort thrombosis has been explained in various ways by different investigators^{84, 85}. It is generally believed that the condition results from compression, torsion or stretching of the subclavian or axillary vein on account of effort involving movements of the shoulder. Many kinds of effort have been blamed, Sampson⁸⁵ having disclosed eighteen different acts that have been reported to precipitate the condition. At times there is no history of effort or injury. Since most persons are right-handed, effort thrombosis is more frequently seen on the right side.

The causes for obstruction of one innominate vein without corresponding obstruction of the other are the same as those for the superior-vena-cava syndrome⁸⁰. In a report of venous-pressure studies in 27 cases of aneurysm of the aorta and innominate artery, it was found that 85 per cent of cases showed preponderant obstruction of one innominate vein⁷⁴. It was pointed out that the left innominate vein has a more intimate relation to the aortic arch than the right, so that it is not surprising that obstruction on the left side predominates in cases of aortic aneurysm.

When there is obstruction of the veins draining blood from one arm, the difference in venous pressures in the two arms ranges from the equivalent of 20 or 30 mm to the equivalent of 300 mm or more of saline solution^{24, 43, 84}. In cases in which obstruction has recently developed, the degree of obstruction can be estimated from the magnitude of the difference in venous pressures, the greater the difference, the severer the obstruction⁸⁴. As a collateral circulation develops, however, the venous pressure on the affected side becomes progressively lower, so that even in cases of complete obstruction of the subclavian vein the pressure may return to the range of normal although not to the level of the unaffected side⁸⁴. In these cases, therefore, the effect of exercise of the hand on venous pressure in the arm is an especially valuable diagnostic adjunct, since the tendency persists for the venous pressure to rise during such exercise on the side of the obstruction⁸⁴.

It has already been mentioned that conditions that alter intrathoracic pressure affect the peripheral venous pressure. In cases of unilateral pulmonary disease without direct involvement of the veins and without attendant change in intrapleural pressure the venous pressure is normal even though the pulmonary lesion is extensive⁸⁶. On the other hand conditions involving one pleural cavity, including pneumothorax, hydrothorax and thoracoplasty, may cause the venous pressure to be higher in the arm on the affected side, presumably because of transmission of increased intrapleural pressure to the innominate vein⁸⁷⁻⁹⁰. Less often this type of lesion causes elevation of venous pressure in both arms⁸⁸, and occasionally the effect is noted only in the arm on the unaffected side, possibly because of shifting of the mediastinum with consequent distortion of the venous inflow tracts of the thorax⁹¹. Usually, the changes in venous pressure that attend pneumothorax and thoracoplasty are transient, subsiding within a few months even though the pneumothorax or thoracoplasty is unchanged⁸⁸. Overholt and Pilcher⁸⁹ have emphasized the fact that in their experience unilateral elevation of venous pressure after thoracoplasty is an unfavorable sign and should cause postponement of additional surgery until the measurements are again normal and equal bilaterally.

Pressure More Elevated in One Foot Than in the Other and Normal in Arms

Occasionally, circumstances warrant the determination of venous pressure at the ankle under basal conditions. The study of Tyson and Goodlett²¹ indicates that when the femoral vein in one leg is acutely occluded by a clot the venous pressure at the same ankle is elevated with the leg at rest. A similar result could be expected when one iliac vein is occluded. Should the ankle pressure be normal and obstruction still suspected, the exercise test described above²² should be performed.

Pressure determinations in leg veins are particularly indicated for evaluation of cases of edema of the lower extremities. If the venous pressure is normal in the lower legs after the exercise test, it can be assumed that the major venous channels are patent and the cause for the edema should be looked for elsewhere.²²

In cases of arteriovenous fistula involving the vessels of the lower extremity, the pressure in the veins near the fistula is elevated, but the systemic venous pressure is normal in the absence of cardiac failure.²³ A similar situation is found when the arm is the site of an arteriovenous fistula.

Dissociation between Pressures in Jugular Vein and General Peripheral Venous System

It has been demonstrated that venous pressures can be determined accurately and safely in the jugular veins. Myerson and Loman²⁴ have described the technic for measuring pressure in the internal jugular vein, and Hitzig²⁵ gives in some detail the procedure of utilizing the external jugular vein for determining pressures. These veins are not generally used except in research studies, the indications for determining the pressure in the internal or external jugular vein being limited. Hitzig²⁵ has demonstrated that this technic is a much more accurate means of studying inspiratory filling of the cervical veins than clinical inspection and palpation.

Loman and Dameshek²⁴ have reported a case of polycythemia with elevation of the internal jugular pressure in both veins to the equivalent of 300 mm of water and with a general venous pressure equivalent to only 80 mm. The initial spinal-fluid pressure was equivalent to 380 mm of water. After venesections totaling 3060 cc of blood in twelve days the pressures in the internal jugular veins and spinal fluid were normal. Apparently, the plethora of this disease was responsible for the increased internal jugular pressure. Other causes of dissociation between pressures in the internal jugular vein and peripheral veins are also discussed by the same authors. Thrombosis of a lateral sinus would be expected to cause a low or absent pressure in the corresponding internal jugular vein. Obstruction to a lower part of the jugular vascular channel could readily produce dissociation with an elevated

internal jugular pressure. An obstructing lesion in the neck or upper mediastinum could readily obstruct one or both jugular veins. An obstructive thrombophlebitis of the internal jugular vein may follow septic throat infections.²¹

The pressure in the antecubital vein may be much lower than that in the veins of the neck in persons with the clinical picture of shock due to sudden onset of severe heart failure.²⁶ Ordinarily, most patients with cardiac failure have a comparable elevation in both the arms and the external jugular veins.

Elevated Portal-Vein Pressure with Normal Pressure in Arm and Leg Veins

The portal-vein pressure may be determined at laparotomy by insertion of the needle of the venous-pressure apparatus into an omental vein or the splenic vein after delivery of the spleen and before ligation of any of the larger splenic veins.²⁶ This technic has proved of value in the study of cases of portal cirrhosis and Banti's syndrome.²⁷ A comparison of the portal venous pressure with the systemic venous pressure—that is, the arm-vein pressure—is particularly valuable. Belli²⁸ found the average normal venous pressure to be 100 mm of saline solution higher than the average pressure in the normal ankle vein, with a range of 140 to 220 mm in contrast to normal ankle pressures of less than 120 mm. In a case of advanced portal cirrhosis with ascites the portal venous pressure was equivalent to 400 mm of saline solution. Thompson et al.²⁹ observed that the splenic-vein pressure ranged from 250 to 500 mm of water in Banti's syndrome with chronic schistosomiasis and from 270 to 470 mm in Banti's syndrome associated with cirrhosis. These figures contrast strikingly with supposedly normal splenic-vein pressures equivalent to 100 to 125 mm of water measured in cases of typical hemolytic jaundice. The arm venous pressures in these cases of Banti's syndrome were essentially normal. It can be concluded that the determination of venous pressures in the splenic vein or in the portal tributary vein is a reasonably accurate although complicated procedure of increasing significance not only in research studies but also in the evaluation of cases for surgical therapy. Blakemore³⁰ has recently suggested that venous-pressure readings, properly taken at operations designed to shunt the portal blood flow in cases of congestive splenomegaly, are an indispensable aid in localizing the site of obstruction in the portal radicles. The effectiveness of a portocaval shunt in such cases can be shown by determination of the portal pressure before and after the shunt is produced. In 4 cases reported by Blakemore³⁰ the pressures were equivalent to 310 to 400 mm of water before and 180 to 240 mm after the shunt was produced.

CASE 33481

PRESENTATION OF CASE

A forty-six-year-old man entered the hospital because of paroxysmal nocturnal dyspnea.

The patient had enjoyed excellent health until five or six years before admission, when he noted the onset of mild exertional dyspnea. During the three years prior to admission he had occasional frontal headaches. Nine months before admission an overpowering feeling of fatigue and severe exertional dyspnea set in, causing the patient to give up work. He was hospitalized at that time, found to have diabetes and put on a dietary regime with 15 units of insulin a day. Subsequently, he felt improved and returned to work. Five months later he consulted another physician, who stated that he no longer needed insulin and placed him on a vegetable diet. He did not do well. During the month before admission several new symptoms developed: paroxysmal attacks of dyspnea occurring almost nightly, orthopnea requiring two or three pillows, marked ankle edema and precordial pain on effort. The exertional dyspnea became very severe, and he was bothered by frequency and nocturia (five times). A week before admission he had marked anorexia and occasional vomiting. He had lost 60 pounds during the present illness.

The patient had no knowledge of hypertension. There had been no tinnitus, epistaxis or vertigo and no kidney symptoms except gradually increasing frequency during the present illness. The alcoholic intake averaged a pint a day for fifteen to twenty years until eight months before admission, but the food intake had always been good. He admitted that he had had gonorrhea five times and syphilis once about fifteen years before entry. The former was treated with irrigations, and the latter with a styptic pencil.

Physical examination disclosed a well developed and well nourished, slightly dyspneic man sitting up in bed. The fundi showed tortuosity of the vessels, hemorrhages, exudates and blurring of the disks. The neck veins were distended and pulsating.

The heart was markedly enlarged with the apex in the anterior axillary line in the sixth intercostal space. There were a Grade III systolic murmur, heard all over the precordium but best heard at the apex, and a blowing diastolic murmur along the left sternal border. The liver edge was smooth and exquisitely tender and extended four fingerbreadths below the costal margin. The spleen was felt three fingerbreadths below the costal margin and was also tender. No ascites was noted. There was marked pitting edema of the ankles.

The temperature was 98°F, the pulse 80, and the respirations 20. The blood pressure was 240 systolic, 160 diastolic.

Examination of the blood revealed a hemoglobin of 14.4 gm per 100 cc. and a white-cell count of 9100, with 88 per cent neutrophils. The urine showed a +++ test for albumin and a negative test for sugar, and the sediment contained occasional hyaline and granular casts and occasional white cells. A blood Hinton test was negative. The nonprotein nitrogen was 48 mg per 100 cc and a phenol-sulfonephthalein test showed 10 per cent excretion of the dye in two hours.

An x-ray film of the chest disclosed left ventricular enlargement and considerable pulmonary congestion. There was probably some fluid in the left costophrenic angle. An electrocardiogram showed left ventricular strain and aortic ventricular block.

During the hospital stay the patient was at first irrational but later lapsed into coma. A lumbar puncture on the eighth hospital day revealed an initial spinal-fluid pressure equivalent to 425 mm of water. The pressure fell to 275 mm with the removal of 8 cc. The fluid contained 2 red cells per cubic millimeter but no white cells. The protein was 80 mg per 100 cc. The serum nonprotein nitrogen gradually rose, reaching 130 mg per 100 cc terminally, with a carbon dioxide of 20.4 milliequiv per liter. The uric acid was 10.1 mg, the calcium 7.5 mg and the phosphorus 4.6 mg per 100 cc. The blood pressure varied between 260 systolic, 190 diastolic, and 205 systolic, 135 diastolic. The respirations were Cheyne-Stokes in character during almost the entire hospital stay. On the seventh hospital day the temperature suddenly rose from normal levels to 100.8°F and thereafter varied irregularly between 100 and 101°F until the twentieth hospital day, when it gradually started to climb, reaching 105.8°F during the next four days. The pulse rate, from the seventh day on, averaged between 90 and 110, with several brief spikes to 110. The respiratory rate was very irregular, varying from 20 to 30. On the fourteenth and fifteenth days cough was a prominent symptom, and thereafter frequent note was made of rales at the bases. The urine never showed more than a few white cells.

The patient died quietly on the twenty-fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR RICHARD J CLARK From this protocol we develop the impression of a definite type of patient. He was a forty-six-year-old man who entered the hospital well nourished, in spite of the fact that he had lost 60 pounds in weight. Evidently he had been obese. He admitted that he had had gonorrhea on five occasions. He gave a history of syphilis, which had been treated with a styptic pencil. He had taken a pint of alcohol daily for twenty years. In spite of this prophylactic medication severe hypertension and severe arterial disease developed. At the outset we may assume by definition that he had malignant hypertension. It is also quite certain that he had congestive heart failure of a severe degree involving both the left and right sides of the heart. In addition, he had severe renal disease and died with a picture of terminal uremia. Perhaps I should stop here and stay out of hot water, but I do find a number of intriguing side issues that are of interest to speculate upon.

In the first place, did the patient have a simple malignant hypertension or possibly a pheochromocytoma? The history mentions glycosuria. We do not know definitely that he had diabetes, although there was at one point sufficient glycosuria to require insulin. At the time of entry to the hospital there was no positive evidence of diabetes. In a patient with hypertension and glycosuria, pheochromocytoma is one of the factors to be considered. Ordinarily, pheochromocytoma is regarded as presenting a paroxysmal type of hypertension, of which there is no definite evidence in the case under discussion. We do know that the diastolic pressure ranged between 135 and 190. Green* has reported a series of 51 patients with pheochromocytoma. The interesting thing is that only 14 presented definite paroxysmal hypertension. The other 37 had sustained hypertension, and 4 of these ran a course of malignant hypertension with death from cerebral vascular accidents, congestive failure and uremia. Some hypertensive patients upon whom sympathectomy has been performed have revealed unexpected adrenal tumors at operation. Apparently, this patient was too sick to have had an intravenous pyelogram done, although this would have been of interest. I see no definite basis on which to make a diagnosis of pheochromocytoma, but such a finding at post-mortem examination would not surprise me.

What about the urinary tract? The patient had very little or nothing in the way of urinary symptoms until approximately a month before death. He had no previous history to suggest acute glomerulonephritis at any time. He did have diabetes, and we might wonder about intercapillary glomerulosclerosis, but so far as I am aware that

has not been described as an accompaniment of the malignant type of hypertension. The same point may be made regarding infections of the urinary tract. The urinary sediment contained only a few white cells, and at no time did he have any appreciable evidence of true urinary-tract infection. He had gonorrhea five times. The amount of frequency (nocturia of five times) in the last month is in some ways a bit more suggestive to me of an obstruction in the urinary tract than it is of a simple renal lesion. Did he possibly have a stricture, or did he have constriction in the region of the prostate causing back pressure? That is a definite possibility, but the symptoms of hypertension developed a considerable time before the urinary frequency, and I cannot conceive of a hydronephrotic picture giving rise to this situation. All in all, the most probable diagnosis so far as the renal tract is concerned is malignant nephrosclerosis.

What about the cerebral status? One of the differential diagnoses of malignant hypertension with encephalopathy is brain tumor. Could the patient have had a brain tumor? He had a high spinal-fluid protein and eye-ground findings that could have been consistent with tumor. On the other hand he had no localizing symptoms and no severe headache. I can see no reason for making a diagnosis of brain tumor in this case and believe that all the findings, including the spinal-fluid pressure and the spinal-fluid protein, are entirely consistent with malignant hypertension and uremia.

Now we come to the heart, which is one of the stumbling blocks along the line. May we see the x-ray films?

DR STANLEY M WYMAN The heart is markedly enlarged, chiefly toward the left and probably chiefly the left ventricle. The aorta is somewhat tortuous. It can be seen in the lateral view, descending close to the posterior chest wall. There is probably a very small amount of fluid in one of the costophrenic sinuses. The hilar shadows are definitely enlarged. Whether this is entirely vascular or whether there are underlying changes in the lymph nodes or possibly in the stem bronchi, I cannot say. We should have two things to verify this point, fluoroscopy and a heavy exposure film. The picture is consistent with congestion, however.

DR CLARK What would you say about the aorta? Do you consider it dilated? Can you define the areas of dilatation if there are any?

DR WYMAN One cannot make an accurate measurement of the diameter of the aorta, except at the arch, where it does not look dilated.

DR CLARK Do you think, from the x-ray point of view, that you can make a reasonable differential diagnosis between left ventricular enlargement in aortic regurgitation and aortic-valve disease as against left ventricular hypertrophy of hypertensive heart disease?

*Green, D. M. Pheochromocytoma and chronic hypertension. *JAMA* 131:1260-1265, 1946.

Dr. WYMAN Not by x-ray study alone This is consistent with hypertensive heart disease, but we certainly see the same picture without the enlargement of the hili in aortic regurgitation

Dr. CLARK The heart was obviously very much enlarged There was a loud systolic murmur at the apex, which might have been due to organic mitral regurgitation, but with the degree of enlargement it probably represented functional regurgitation The next item is the diastolic murmur heard clearly along the left sternal border We can say definitely that this patient did not have free aortic regurgitation He had no wide pulse pressure and no drop in diastolic pressure Syphilitic heart disease may be engrafted upon hypertensive heart disease Did this patient have syphilitic aortitis or aortic-valve involvement in addition to the hypertensive heart disease? The blood serologic findings were normal Is the spinal-fluid Wassermann test recorded?

Dr. TRACY B. MALLORY No

Dr. CLARK In cardiovascular syphilis the serologic reaction is positive in 85 per cent or more of cases This man was relatively young, and I believe that if syphilitic aortic regurgitation had been developing, which would have occurred in the early developmental stage, the serologic reaction would have been positive Beyond that, the story of syphilis is quite uncertain Certainly, syphilitic aortic regurgitation could not have accounted for the dyspnea of several years' duration such as this patient had, without being much more full blown than it was I shall therefore discard any diagnosis of syphilitic involvement of the heart.

Could he have had rheumatic heart disease along with hypertensive heart disease? Such a combination is common From the x-ray film, if he had rheumatic heart disease, it must have been primarily aortic-valve disease There was no past history of heart trouble or rheumatism That does not rule out the diagnosis, but on the law of chances I shall let it go by the board

How about pulmonary regurgitation giving rise to the murmur? That is a possibility What about hypertension and hypertensive heart disease as possible causes? The electrocardiogram showed definite left ventricular strain and was consistent with hypertensive heart disease. We know from certain series of cases that aortic regurgitation occurs in conjunction with hypertension in between 25 and 7 per cent of cases, without assuming any other disease of the aortic valve. This apparently arises from dilatation of the aorta and aortic ring If that situation ever occurs, it may well have been present in this case with a considerably dilated heart and a tremendous rise in diastolic blood pressure

I shall hold to my original diagnosis of hypertensive heart disease. In addition, I believe that post mortem examination revealed definite evidence

of coronary-artery disease The patient had precordial pain on exertion during the last year of life, and also in the electrocardiogram he showed delayed auriculoventricular conduction These two factors are reasonable evidence on which to make a diagnosis of coronary disease

There is one more problem in this museum of difficulties—namely, the enlarged liver and spleen If we go back in the history we realize that the patient had been taking alcohol in large doses for twenty years Did he have cirrhosis of the liver in addition to the other troubles? Early cirrhosis may produce a nodular liver such as that described, but I am not aware that cirrhosis of the liver ordinarily causes a tender liver The liver described in this case is consistent with the liver of congestive heart failure, and without any other definite evidence to tie to, I shall consider it as such

The matter of the spleen is not quite so easy The patient had no anemia on entry There was no evidence of any blood dyscrasia and no abnormal adenopathy or anything of that sort to associate the spleen with In a cardiac patient with splenic enlargement, particularly with a tender spleen, the first thing to consider is subacute bacterial endocarditis I have already ruled out the ordinary cardiac lesions upon which subacute bacterial endocarditis is usually engrafted Against subacute bacterial endocarditis was the absence of fever on entry or other corroborative physical findings What about splenic infarction? This is one of the other conditions in heart disease that one must consider as a cause for splenic enlargement, but there was no history to substantiate such an episode There are debates about the occurrence of palpable splenic enlargement from passive congestion Some authors state that it never occurs except occasionally in childhood Others say that it occurs on occasion I shall assume that the splenic enlargement in this case was on the basis of a fairly severe degree of passive congestion

What about the terminal episode? The patient was febrile during the last two weeks in the hospital There was no evidence of increasing urinary-tract infection His exitus was a gradual one, without any sudden episode I believe that he developed a terminal bronchopneumonia

Finally, is there any other single diagnosis that can tie up this myriad of findings and symptoms apart from those that I have mentioned? The only one that I can think of is periarthritis nodosa There are a number of problems that present themselves with this diagnosis Periarthritis ordinarily runs a relatively rapid course and yet may drag out over a considerable period, but I cannot conceive of its continuing for five years There was an acute exacerbation, with the appearance of new symptoms, a month before entry It is possible that periarthritis nodosa set in at that point. Periarthritis is usually a febrile disease throughout,

whereas this patient had fever only terminally. It usually causes a leukocytosis, which was lacking, although examination of the blood revealed 88 per cent neutrophils. He did not show an eosinophilia, but this is by no means essential to the diagnosis. All in all, I consider periarteritis nodosa a remote possibility.

I shall conclude essentially where I started, with the belief that this man had an acute malignant hypertension, possibly based on a pheochromocytoma, associated with malignant nephrosclerosis and uremia, as well as hypertensive and coronary-artery disease with congestive failure.

CLINICAL DIAGNOSES

Malignant hypertension
Uremia

DR CLARK'S DIAGNOSES

Malignant hypertension
Pheochromocytoma?
Malignant nephrosclerosis
Hypertensive and coronary-artery disease
Congestive heart failure
Terminal bronchopneumonia

ANATOMICAL DIAGNOSES

Nephrosclerosis
Hypertrophy of heart
Multiple pulmonary emboli, with pulmonary infarction
Chronic passive congestion
Thrombophlebitis, left leg
Mural thrombus, right auricle

PATHOLOGICAL DISCUSSION

DR MALLORY Post-mortem examination demonstrated a greatly enlarged heart, which weighed 750 gm, with apparently normal valves and an aorta that showed very little atheroma and no suggestion of syphilitic scarring. The coronary arteries contained a few flecks of atheroma but no points of significant narrowing. Nevertheless, the myocardium revealed a few minute, microscopic foci of absorption of muscle cells although no gross infarction. A marked degree of nephrosclerosis was found in the kidneys. From the histologic point of view they did not show any of the stigmas of malignant hypertension. There were no changes in the glomeruli and no necrosis of the walls of the blood vessels. This does not surprise me very much, since I have never been able to make a satisfactory correlation between the so-called "clinical malignant hypertension" and the so-called "pathological malignant hypertension." Usually, the pathological findings are consistent in patients who die in uremia in contrast to those who die in cardiac failure or from cerebral accidents. Since this patient was certainly approaching uremia at the time of death, I am a little surprised that the

findings were not present, but there was no trace of them. The brain was essentially normal. There was no obstruction in the urinary tract.

The surprise of the autopsy was the presence of four massive pulmonary infarcts each in a separate lobe of the lung, and I believe that those were the cause of the terminal fever—at least we found nothing else to explain it. There was evidence that there had been multiple pulmonary emboli, some much older than the ones that caused the infarcts. The liver was enlarged and showed only passive congestion. The spleen weighed 490 gm, which is a marked degree of enlargement for chronic passive congestion, but we found no other explanation for it.

DR CLARK How often do you find enlarged spleens at post-mortem examination from passive congestion and heart disease?

DR MALLORY Almost always, but rarely enough enlargement to make us confident that they were palpable. A few years ago I checked over quite a series of cases of splenomegaly, and unless the spleen weighs 400 gm it is rarely felt. It must be three times the normal size before one begins to feel it. The spleen in this case was distinctly larger than that.

DR CLARK This case emphasizes a point that I should certainly have mentioned in any patient with chronic heart failure in whom one suspects bronchopneumonia, one is probably wrong, it is usually pulmonary infarction.

DR MALLORY Possible sources of the thrombi were the deep veins of the leg and the calf, and also a thrombus in the right auricle of the heart. I cannot say from which source the pulmonary emboli came.

A PHYSICIAN Was any bacteriologic examination done?

DR MALLORY Yes, it was entirely negative.

CASE 33482

PRESENTATION OF CASE

First admission A fifty-six-year-old man with a six-year history of attacks of wheezing and dyspnea was admitted to the hospital during an exacerbation of asthma.

He had had severe cough and wheezing for two weeks, requiring adrenalin two or three times a day. The dyspnea had prevented sleep. The cough had produced about a cupful of yellow sputum a day, but he had had no fever. He admitted exertional dyspnea for four or five years and had been unable to work for two years. He denied any definite allergy. A maternal grandmother had had asthma.

Physical examination showed a cyanotic, obese man with a barrel-shaped chest. Respiration was shallow and almost entirely diaphragmatic. There were coarse "squeaks" over both lung fields. Moist

rales were present bilaterally. The heart sounds were distant, and the blood pressure was 130 systolic, 80 diastolic. The liver edge was palpated 7 cm. below the costal margin, the upper border being at the sixth rib. There was moderate pitting edema of the ankles.

Examination of the blood revealed a red-cell count of 4,550,000, with a hemoglobin of 9.7 gm., and a white-cell count of 17,200, with a normal differential. The urine showed a +++ test for albumin and had a specific gravity of 1.016. The sediment contained 30 red cells and 40 white cells per high-power field, as well as granular casts. An electrocardiogram showed a normal rhythm at a rate of 80 to 90, with small Q waves in Leads I, CF, and CF₄. A phenolsulfonephthalein test showed 30 per cent excretion of the dye in half an hour and 70 per cent in two hours. The nonprotein nitrogen was 50 mg. per 100 cc.

An x-ray film of the chest disclosed scattered areas of fibrosis in both lung fields. The hilar shadows were moderately enlarged, and there was an area of soft mottled density in the middle portions of both lung fields and at the bases. There was a small quantity of fluid in each pleural cavity.

The patient improved slowly with adrenalin, aminophylline, a low-salt diet and sedation. The urinary sediment showed 200 red cells and 12 white cells per high-power field. He was discharged unimproved on the thirteenth hospital day.

Final admission (ten months later). The dyspnea and cough, which was productive of about a pint of yellow, sometimes blood-streaked sputum, persisted. Nocturia (four times), developed without other urinary symptoms. Three weeks previously the dyspnea and asthma had increased, and twitching movements of the face and extremities had developed.

Examination revealed an extremely ill, cyanotic man. Numerous coarse rales were audible at the left base. Dullness and diminished breath sounds were present at the right base. There were no cardiac murmurs.

The temperature was 99.6°F., and the respirations were 35 to 40. The blood pressure was 180 systolic, 100 diastolic. The pulse was 110 and regular.

Examination of the blood revealed a hemoglobin of 7.5 gm. and a white-cell count of 12,000. The urine gave a ++ test for albumin and had a specific gravity of 1.012; the urinary sediment contained numerous red cells, white cells and casts. The nonprotein nitrogen was 60 to 85 per 100 cc., the blood calcium 7.6 mg., and the phosphorus 17.0 mg. The phosphatase was 5.4 units. An electrocardiogram showed a normal rhythm (100), a PR interval of 0.14 second and a tendency to left-axis deviation. The Q waves were small and the T waves were upright in Leads I and 2.

In spite of digitalization, aminophylline, a washed-red-cell transfusion and other supportive measures the patient died in marked respiratory difficulty on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR MYLES P. BAKER. With the facts at hand it seems to me that the house-officer writing a discharge summary at the end of the first admission must have had some doubt regarding just what he had been dealing with in this patient. It is the story of a cyanotic, asthmatic patient who had had attacks of wheezing dyspnea for years and in whom, with a presumptive diagnosis of bronchial asthma, adrenalin had given definite relief. He was later admitted with signs of bronchiectasis and, by description, an emphysematous chest. The question probably came up on admission whether a superimposed bronchial infection was involved or whether there was an element of heart failure, particularly right-sided heart failure, in view of the cyanosis, the apparent enlargement of the liver and the ankle edema. There was a noteworthy absence of hypertension. With further study the electrocardiogram proved to be not that typical of chronic cor pulmonale, with the development of a prominent S wave in Lead I and a prominent Q wave in Lead 3, and there were no inverted T waves in the first chest leads. Nor have we certain evidence of cardiac failure. The liver may have been low because of the emphysematous chest. The upper border may have been at the sixth rib. The man was obese, and it is difficult to feel a liver in such a patient who is breathing rapidly. The edema of the ankles may have been due to obesity and local lymphatic obstruction and not to myocardial insufficiency. The finding of evidence in the urinary sediment of a renal lesion is important and is emphasized in this protocol by the statement that on discharge the patient had a persistent and unexplained hematuria. He had renal insufficiency to judge from the one phenolsulfonephthalein test. He had anemia, for which we have no explanation. The leukocytosis may be explained on the basis of bronchiectasis, but that is not definitely established.

The x-ray examination of the chest is important in arriving at a diagnosis. I suggest that Dr Wyman show these films.

DR STANLEY M. WYMAN. The first two sets of films show mottled density in the upper lung fields, particularly on the right. This is essentially unchanged in the two films taken five months apart. There is a suggestion of some mottling in the left midlung field. I cannot be sure of the disease in the lower lung fields, although there is a suggestion in one or both of the lower lobes. The fluid described in the costophrenic sinuses is not impressive. The heart does not appear to be enlarged, it has no characteristic configuration. The aorta is not remarkable. I can see no definite hilar or mediastinal

masses The last film, which was taken five months after the first, shows a marked change The heart now appears to be definitely enlarged, and the enlargement seems to be chiefly left ventricular There is a good amount of fluid in the right pleural space The upper lung fields now show mottled density as on the first examination, with new hazy density in the lower lung fields on both sides, probably in the lower lobes

DR BAKER The picture on admission is not that of a prominent pulmonary conus?

DR WYMAN No, the hilar shadows are prominent, but there is no definite enlargement of the base of the pulmonary artery Along the upper heart borders I cannot see any essential change in the appearance of the hilar shadows in the last observation The main changes have taken place in the lung fields and in the heart size

DR BAKER This patient was not treated with diuretics and apparently not digitalized and was probably discharged with the diagnosis of bronchial asthma and a renal lesion of undetermined nature — that is, probably, some form of nephritis The most significant features about the final admission are the relentless progress of the disease toward the uremic picture with which he entered the hospital, the rising blood nonprotein nitrogen to confirm this impression, the progressive anemia and the appearance for the first time of arterial hypertension

The question of diagnosis seems to me to boil down into one or two possibilities This man may have had bronchial asthma that had been developing in an insidious fashion, in addition to a renal insufficiency that had contributed to his increasing disability of the past few years and ultimately proved fatal, this renal insufficiency being due to one of the usual causes — glomerulonephritis, essential hypertension or pyelonephritis — or to one of the rare causes, such as polycystic kidneys There is another possibility that would account for both bronchial asthma of years' standing and renal failure, namely, periarteritis nodosa

In the few moments that remain we should go a little farther into that possibility About seven or eight years ago Dr Rackemann¹ reported briefly on eight cases with a combination of bronchial asthma and periarteritis nodosa, four of which died and four were living He noted that Dr Greene had reviewed the literature of periarteritis nodosa and found that 8 per cent of patients had asthma, presumably bronchial asthma, although in the discussion of the paper some question was raised whether some of the cases of asthma were cardiac, rather than true allergic cases A few years before 1936 some observers reported 3 cases of apparently "run of the mill" asthmatic patients who became worse, began to run fevers, developed some of the diverse symptoms of periarteritis nodosa, such as cutaneous manifestations and polyneuritis or renal failure, and died² In the larger reported series of

cases of periarteritis nodosa there are usually 1 or 2 in which bronchial asthma is either the chief complaint on admission or very prominent in the past history The x-ray picture of the chest in this patient as described in the protocol sounds very much like a few lesions demonstrated by chest x-ray study in cases of periarteritis nodosa I must say that the x-ray findings as Dr Wyman demonstrates them are not what is described in these well studied cases³ In periarteritis nodosa there is usually a more extensive involvement of the hilar region, and a picture consistent with small pulmonary infarcts rather diffusely distributed through the lower lobes, with small pleural effusions I believe that the development of hypertensive heart disease in the course of a year is important In a report of cases of periarteritis nodosa from Johns Hopkins Hospital this point was stressed, the authors mentioning that 1 or 2 patients had variable blood-pressure levels, at first moderately high, then normal and then rising rapidly toward the end to high levels at the time of death from bronchopneumonia⁴ The absence of any hypertension ten months prior to this man's death, at a time when he had diminished renal function and hematuria, otherwise unexplained by a lesion in the lower urinary tract, is much against death from glomerulonephritis

Glomerulonephritis without hypertension, even in very late stages, is rare It may occur during the latent stage This man did not have a latent lesion on first admission to the hospital Even in the absence of some of the more accepted manifestations of periarteritis nodosa, such as peripheral neuritis and coronary insufficiency, I put that disease down as my diagnosis because of the absence of any other good cause for the renal insufficiency and because of the association with chronic bronchial asthma and the rapid progress of the disease and its terminal phase to uremia

DR TRACY B MALLORY Dr Burrage, would you tell us your impression?

DR WALTER S BURRAGE I must confess to being the one who had difficulty in writing the discharge diagnosis at the termination of the first hospital entry There are a few points of interest in addition to what Dr Baker has brought out In the first place this patient had a six-year history of asthma with onset at the age of fifty and with no premonitory symptoms This presumably places him in the so-called "intrinsic group" It was therefore not surprising to find that the intracutaneous tests were negative He was cyanotic from the onset, had clubbed fingers and later developed edema of the ankles The hemoglobin was originally 65 per cent, with a red-cell count of 3,100,000 He never had hypertension during the early stages Fluoroscopy was done on several occasions in an effort to differentiate the role of cardiac failure and pulmonary infection as complications of the asthma These examinations demonstrated a heart of rela-

nely normal size, but later ones in particular showed definitely increased lung markings radiating to the bases, which, with the purulent sputum, suggested the possibility of severe chronic bronchitis or even bronchiectasis.

We discussed periarteritis nodosa, but decided against it. The red cells that were always present in the urine were in favor of it as well as of nephritis, but there were none of the multiple symptoms that these patients often have. We also had difficulty in arriving at a diagnosis but finally decided on chronic nephritis, intrinsic bronchial asthma, severe chronic bronchitis and questionable bronchiectasis.

DR MALLORY Dr Lerman, have you an opinion?

DR JACOB LERMAN I saw the patient on the last admission when he entered in severe congestive failure. He had a long-standing asthma with pulmonary fibrosis and infection. We considered the possibility that the shadow on the right side was consolidation, pneumonia or, more likely, infarction, and discussed the question of vein ligation, but did not carry it out because he was in poor condition. So far as renal disease is concerned, there was the possibility of pyelonephritis. Two urine cultures were reported one contained pyocyanous bacilli, and the other abundant colonies of *Staphylococcus albus*. We were uncertain about blaming the renal picture on chronic pyelonephritis. We considered periarteritis nodosa but decided that this diagnosis was untenable without further evidence. One other possibility as a cause of the uremia occurs to me—that is, amyloid disease resulting from long-standing infection. The patient must have had pulmonary emboli in addition to the pulmonary infection of long standing.

DR BAKER The absence of eosinophilia is worth commenting on. It should be emphasized that it is found in less than 20 per cent of cases of periarteritis nodosa.

CLINICAL DIAGNOSES

Bronchial asthma
Cor pulmonale

Hypertensive and arteriosclerotic heart disease.
Chronic nephritis

DR BAKER'S DIAGNOSIS

Periarteritis nodosa

ANATOMICAL DIAGNOSES

Subacute glomerulonephritis
Pulmonary emphysema
Bronchiectasis, right upper lobe
Bronchopneumonia, terminal
Cardiac hypertrophy
Arteriosclerosis, generalized, moderate

PATHOLOGICAL DISCUSSION

DR MALLORY At autopsy the lungs presented a complicated picture. There was extensive bronchiectasis. There was severe pulmonary emphysema, with patchy fibrosis of the lungs, and in both lower lobes there was a very extensive organizing pneumonitis of comparatively short duration—perhaps a few weeks or months, I should estimate.

The next point of interest was the kidneys, which were greatly enlarged, weighing 580 gm. The surfaces were rather pale and dotted with petechial hemorrhages. On microscopical examination there was a typical subacute glomerulonephritis. From the histologic point of view it looked even more acute than subacute. The heart was very markedly hypertrophied, weighed 680 gm. In none of the organs did we find any lesion suggestive of periarteritis nodosa so that subacute glomerulonephritis was probably the chief cause of death.

DR CHARLES L. SHORT Was this cor pulmonale?

DR MALLORY No, in cor pulmonale a diffuse hypertrophy of all chambers, most marked on the left, is observed.

Mr John E Farrell, executive secretary-treasurer, presented a report in which he called attention to the formation of a conference of the officers of the New England State Dental Societies, and suggested that the Council might extend an invitation to meet with this dental group at some future date

Dr Joseph Howard commented on the meeting of the National Physicians Committee held in Chicago in September, which was attended by either medical or dental representatives from each of the forty-eight states. The tone of the conference emphasized the communistic inroads made in the country rather than the socialization of medicine

Mr Farrell reported that the radio program "Doctor's Orders," initiated in Providence in 1944, with the co-sponsorship of the Rhode Island Medical Society, is now to be carried over the Yankee Network in New England. The Council recorded itself as approving the program

After reports from the various state representatives, discussion took place regarding a public-relations conference, and the Council voted unanimously that such a meeting be held in Boston, probably on March 7, 1948

Dr John F Conlin, director of medical information and education of the Massachusetts Medical Society, then described the antivivisection situation in New England, and Dr Robert Fleming, chief of the Out-Patient Clinic for Alcoholism at the Peter Bent Brigham Hospital, spoke on "An Out-Patient Approach to the Treatment of Alcoholism"

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

REACTIONS TO ANTIRABIC VACCINE

Physicians have so many prophylactic and therapeutic agents for which they are continually having to weigh indications against contraindications that it is most difficult to keep currently informed regarding agents that are used only on rare occasions

Some physicians lose sight of the fact that extremely careful evaluation should be made of every situation in which it appears that the administration of antirabic vaccine is indicated to a person bitten by a dog. Within ten months, there have been 2 fatal cases following the administration of antirabic vaccine in the Commonwealth. These incidents emphasize the fact that all indications and contraindications should be weighed before antirabic vaccine is given. There is a very real danger in the administration of this vaccine. Some kind of reaction usually occurs in about 1 case in 500, and death results in about 1 case in 25,000

In recent months, letters from the Department recommending treatment of persons bitten by dogs

have carried a stamp calling attention to the low prevalence of rabies and suggesting that the vaccine can be withheld in many cases in which it was formerly considered mandatory. Beginning early in September, this stamp was no longer placed on the letters going into Berkshire County because rabies is apparently prevalent among wild animals in New York State along the western border of Massachusetts. A rabid fox has also been found just inside the western border of Connecticut

During the last three years rabies has been an increasing problem in a band of states including New York, Pennsylvania, Maryland and Virginia, as well as in the District of Columbia. During 1943, 1944 and 1945, a total of 5604 rabid animals were found in these states, compared to 1026 in the years 1940, 1941 and 1942. In New York State alone the increase was from 474 cases to 1202

By widespread immunization of dogs with antirabic vaccine, the disease in dogs has been materially reduced, but the wild animals of the State of New York have become infected, particularly foxes and skunks. These animals have been biting domestic animals so that many herd owners have found it necessary to immunize their cattle against rabies

The situation in New England has been much more satisfactory. During the three years, 1940, 1941 and 1942, the number of rabid animals discovered in New England was 222, compared to only 10 during the years 1943, 1944 and 1945. Endemic rabies has apparently been absent from Massachusetts for over two years, and it is believed that wide use of antirabic vaccine among dogs has been largely responsible for reducing the disease from the high level of 1930

It cannot be too strongly emphasized that rabies vaccine should never be given to human beings unless it is strongly indicated. Physicians who are in doubt regarding a particular case will do well to call the Division of Communicable Diseases of the Massachusetts Department of Public Health for current information and recommendations

NOTICES

NEW ENGLAND DERMATOLOGICAL SOCIETY

A regular meeting of the New England Dermatological Society will be held at the Boston City Hospital on Wednesday, December 3, at 2 p m. This meeting is open to members and invited guests

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, December 4, at 7 15 p m in the classroom of the Nurses' Residence. The subject "Meconium Ileus" will be discussed. Dr Gertrude Cone will be chairman

LATENT RHEUMATIC MYOCARDITIS*

JOSEPH ROGERS, M.D.,† AND STANLEY L. ROBBINS, M.D.‡

BOSTON

RHEUMATIC fever, a systemic disease affecting chiefly the heart, has always been considered to be primarily a disorder of childhood with a markedly diminished incidence of initial and recurrent attacks after puberty.^{1,2} At the younger age levels rheumatic fever follows a variable but usually recognizable pattern, with carditis, arthralgia, chorea and subcutaneous nodules as major manifestations and with fever, abdominal pains, skin rashes, epistaxis and changes in the electrocardiogram, sedimentation rate and white-cell count as minor manifestations of the disease.³

It is also appreciated, however, that all these features may be absent in any individual case and that characteristic signs of rheumatic valvular disease may be found in persons from whom no previous history of rheumatic fever can be elicited. In children, the only manifestation of recurrent acute rheumatic carditis is frequently the insidious onset of right-sided cardiac failure, the nature of which has been described by Walsh and Sprague.⁴

Less well known, however, is the fact that initial as well as recurrent acute attacks of rheumatic carditis occur in the later years of life, and at these age levels they may arise in the complete absence of characteristic clinical signs, progressing insidiously into acute cardiac decompensation and death.

It is therefore not uncommon for the activity of these processes — more specifically, the myocarditis component — to be completely unsuspected during the life of older patients. Usually, these cases are considered to be instances of cardiac decompensation arising out of the mechanical impairment of the normal valvular function incurred in earlier attacks of rheumatic carditis.

Many reasons exist for the frequency of acute rheumatic myocarditis as a clinically unsuspected

entity in older age groups, the most important of which, perhaps, is the lack of widespread appreciation of the significance of acute rheumatic myocarditis as a fundamental cause of cardiac decompensation in the rheumatic state. Although the point is still a moot one, a number of authors⁵⁻⁷ agree that the factor precipitating cardiac failure in patients with old rheumatic heart disease is often a reactivation of the rheumatic myocarditis. Rothchild, Kugel and Gross,⁸ who have directed attention to this point, make the following observation: "While the causal relationship of active myocarditis to circulatory failure is very striking in the first two decades of life, it is not sufficiently appreciated that in cases of rheumatic heart disease in adults of the third, fourth and fifth decades of life a recurrent rheumatic myocarditis rather than the healed mechanical defects may in the majority of instances be the precipitating cause of circulatory failure." They also point out that a number of patients who have had rheumatic heart disease that has become completely quiescent reach the fifth, sixth, seventh and even the eighth decades of life and ultimately die of a totally unrelated disease without any evidence during life of myocardial failure directly attributable to the mechanical defects of old rheumatic infection.

Another reason for the failure to recognize acute rheumatic myocarditis as a clinical entity in adults is the comparative infrequency with which active rheumatic carditis produces decompensation compared to hypertension, arteriosclerosis and inactive rheumatic heart disease. Only an acute awareness of its possible occurrence will permit its recognition. Finally, in many cases, the disease is completely asymptomatic, and no diagnosis is possible short of anatomic investigation of the heart.

Attention having been directed to several cases of active rheumatic carditis in which the correct diagnosis was not made clinically, a study was made of all the cases of acute rheumatic myocarditis coming to autopsy at the Mallory Institute of Pathology of the Boston City Hospital from 1933 to 1946

*Presented at a meeting of the New England Heart Association, Boston, January 27, 1947.

†From the First and Third Medical Services and the Mallory Institute of Pathology, Boston City Hospital.

‡Assistant resident in medicine, Third Medical Service, Boston City Hospital.

Assistant professor of pathology, Boston University School of Medicine; instructor in pathology, Tufts College Medical School; instructor in pathology, Harvard Medical School; assistant pathologist, Mallory Institute of Pathology, Boston City Hospital.

Specifically, it was desired to determine how often patients with known rheumatic heart disease considered to be inactive clinically are found to have active cardiac disease at autopsy, how often acute rheumatic fever occurs as a true latent disease—that is, in the absence of the usual clinical mani-

SELECTION OF CASES

The microscopical sections in all cases listed as active rheumatic myocarditis at the Mallory Institute of Pathology in the thirteen-year period from 1933 to 1946, together with the autopsy protocols, were reviewed to obtain a series of proved cases of

f activity, what factors, in retrospect, contributed to a more accurate diagnostic rheumatic disease, and how frequent rheumatic myocarditis occurs without associated rheumatic valvular or peri-

active rheumatic myocarditis. Cases of superimposed acute or subacute bacterial endocarditis were eliminated because of the possibility that the Aschoff bodies were related to the endocardial bacterial infection.^{8, 9} Forty-one cases were demonstrated to have characteristic Aschoff bodies in the

myocardium and were available for study. On review of the clinical records, it became apparent that cases of rheumatic myocarditis could be divided into four groups.

Group I comprised 20 cases in which the clinical and pathological diagnoses of active rheumatic fever

post-mortem examination were found to have active rheumatic myocarditis as evidenced by the presence of Aschoff bodies in the myocardium, in addition to the characteristic rheumatic valvular deformity.

Group III included 7 cases in which no diagnosis of rheumatic heart disease, active or inactive, was

and 16 female patients. Each of the four groups is considered individually below.

Group I

In Group I the average age was eighteen years, with a range from two to fifty-three years (Table 1). It is significant that only 5 patients were over fifteen years of age.

Eleven patients had had at least one previous episode of rheumatic fever. Sore throat, upper respiratory infection or scarlet fever preceding the rheumatic episode was a prominent feature, being present in 14 cases. Two patients had had no preceding infection, and in 3 cases the record did not indicate whether or not there had been a previous infection. Joint pains or actual polyarthritis was prominent, being found in all but 5 cases. Four patients complained of abdominal pain. Thirteen patients had presented evidence of pericardial in-

volvement, manifested either by the presence of a friction rub or by actual pericardial effusion. Although not recorded in Table 1, a forceful heaving cardiac apical impulse was common. All but 2 patients had congestive failure, and all had fever. Elevated sedimentation rates were found in all but 2 of the 11 cases in which the test was performed. White-cell counts were consistently elevated, and electrocardiograms taken on 12 patients showed

PR intervals in the upper limits of normal in 4 and prolonged in 5. In short, the clinical evidence was sufficient to permit recognition of rheumatic activity. At autopsy all the hearts of the patients in Group I, in addition to active myocarditis, showed either old healed rheumatic valvular deformities or acute rheumatic endocarditis, or both. In 8 cases an acute valvulitis was superimposed on an earlier healed process. In every case there was definite anatomic evidence of cardiac decompensation, which was considered to be the cause of death in all but 1.

Group II

In Group II the average age was forty-one years, with a range from twelve to sixty-three years (Table 2). It is significant to note that on the average these patients were twenty-three years

older than those in Group I. Previous episodes of rheumatic fever were noted in all but 2 cases in Group II. Five patients had had episodes of congestive failure. In contrast to the frequency of sore throats or upper respiratory infection in Group I, only 3 cases in this group presented evidence of such preceding infections. Joint phenomena were also less striking, only 3 of the 10 patients complaining of recent joint pains. One patient had

From the pathological point of view autopsy demonstrated the classic lesions of rheumatic heart disease in all cases. In addition to the active myocarditis, all the hearts presented typical healed aortic or mitral valvulitis, or both, with stenosis. In 2 cases with old healed valvular deformities a superimposed recurrent acute rheumatic endocarditis was demonstrated by pinpoint fibrinous vegetations along the free margins of the mitral valve. In 9

complained of pains for the previous twelve years. Two patients had had no joint pains for several months, and in the remaining 4 cases joint pains were not mentioned. Typical polyarthritus was not observed in any of these cases. Signs of pericarditis, which were common in Group I, were absent in Group II except in a case in which there was a question of a friction rub. All the patients in this group had murmurs characteristic of valvular damage, and all had congestive failure. The temperatures were normal in 4 cases, and in only 4 cases was there rise to over 101°F. Sedimentation rates were determined in only 4 cases and were elevated in 3. The white-cell counts were in general lower than those in the group clinically diagnosed as active. Electrocardiograms were recorded in 8 cases. The PR interval was prolonged in 2 and normal in 2 cases. Three patients were fibrillating, and 1 had complete block.

patients the death was attributable to the decompen- sated rheumatic carditis. The remaining pa- tient died of a cerebrovascular accident with signs of cardiac decompensation at autopsy.

Group III

The average age of the patients in Group III was fifty-five years, with a range of twenty-nine to sixty-three — an average of seventeen years older than the patients in Group II and thirty-seven years older than those in Group I. All but 2 pa- tients in Group III were over fifty-nine years of age. The histories had no significant points in common, and such factors as sore throat and joint phenomena were not present except in 1 case (Table 3). Peri- carditis was absent in 6 cases. In only 1 case was there any cardiac murmur suggestive of rheumatic disease. Three patients had given clinical evidence of congestive failure, which was attributed in

2 cases to hypertension, the third being considered arteriosclerosis. It is significant that the sedimentation rates were not determined in any of these patients and that electrocardiograms were taken in only 1 case. The clinical diagnoses in the cases with congestive failure were hypertension and cerebral hemorrhage in 1 case and hypertension with subarachnoid hemorrhage in another, whereas in a third no etiologic cause of failure was given.

At post-mortem examination the hearts were as characteristic of rheumatic heart disease as those in the preceding two groups. In the myocardium there were numerous Aschoff bodies, which, together with the typical healed valvular deformities, made the diagnosis of rheumatic carditis certain. In several cases the Aschoff bodies appeared to be

tion attributed to hypertension, and the other of cerebral encephalomalacia.

DISCUSSION

Of the 41 patients presented, the first group, composed of 20 patients, represented the pathologic process in its familiar clinical form. All the patients except 4 were in the first two decades of life, and they demonstrated at various times during the illness one or more of the typical manifestations. This group serves as a contrast to the other three groups, in which the presence of rheumatic activity was not recognized during life.

The second group of patients, 10 in number, differed from the first group in many respects (Table 5). To begin with, although they were all

somewhat acellular, indicating that the process had passed through the peak of its acuteness, but sufficient necrosis persisted to warrant their inclusion with the cases of acute myocarditis. In 2 patients only an acute valvulitis was present, with no evidence of earlier damage. Two cases presented recurrent acute endocarditis superimposed on old valvular damage.

From the anatomic point of view it appears highly likely that 3 of these patients died of cardiac decompensation, the other 4 dying of massive pulmonary embolism, mesenteric thrombosis, pulmonary tuberculosis and adhesive pericarditis respectively.

Group IV

In Group IV the average age, which was fifty-six years, was the same as that in the cases in Group III, with a range of forty-nine to sixty-two years (Table 4).

One patient had had a questionable diastolic murmur, and 2 had had congestive failure. As in Group III the histories disclosed nothing to point to rheumatic disease, and the clinical diagnoses again were such as to show no relation to rheumatic heart disease. The acute myocarditis was associated with acute yellow atrophy of the liver in 1 case and with bilateral advanced tuberculosis in another. Of the remaining 2 patients, 1 died of cardiac decompensa-

tion known to have had rheumatic heart disease and all were in congestive failure, the disease was considered to be inactive at the time of death. The decompensation was thought to be purely on the basis of previous valvular damage, no element of reactivation of the disease being suspected.

The question obviously arises why this reactivation of the rheumatic carditis was not recognized clinically. The patients as a group gave almost no history suggestive of activation of the disease. Unlike the earlier recognized attacks, the last one was not ushered in with any striking suggestive features such as polyarthritides and sore throat. Perhaps the factor most largely responsible for the failure to recognize active rheumatic heart disease in this group was the age of the patients. As mentioned above, they were at least twenty years older than those in Group I. In 7 cases it is apparent from the clinical records that active infection was not considered to be sufficiently likely to merit close observation of the sedimentation rate and the PR interval. Hence one or both of these important characteristics of active infection are missing from many of the records. Two cases with adequate observations on temperature, sedimentation rate and PR interval may properly be classified as sub-clinical infections. Although occasionally these 2 cases showed transient temperature elevation or

temporary rises in the sedimentation rate, at no time was there any conclusive evidence of activity from the standpoint of history, physical examination or laboratory study. The cases in this group contrast rather strikingly with those presenting initial rheumatic attacks occurring in persons over sixty years of age reported by Ferris and Myers¹⁰ and others,^{11, 12} who found even in these older age groups most of the usual manifestations of active rheumatic disease, such as joint pains and polyarthritides. In many cases, however, the clinical diagnosis was not made because of advanced age. In our cases, which were similar to those reported by Hawking¹³ and others,¹⁴ activity was present in the absence of the usual clinical signs or with only isolated manifestations.

It is perhaps worth emphasizing at this point that in patients of this age group the diagnosis of active rheumatic heart disease not infrequently depends on minor and often single rheumatic manifestations.

Further evidence of the latency of acute rheumatic myocarditis is brought out by the cases in Group III, in which the presence of rheumatic heart disease was not suspected. As can be seen from Table 3, all these cases presented definite evidence of rheumatic heart disease at autopsy, 5 with old healed valvulitis acquired at an earlier attack, and 2 apparently occurring as an initial attack. The recognition of active rheumatic carditis in these cases was rendered many times more difficult by several factors: the absence of a previous history or present evidence of rheumatic fever, the advanced age, 5 of the 7 patients being approximately sixty years old, and the complicating presence of arteriosclerosis or hypertension, which appeared to offer an adequate explanation for the cardiac failure. Strangely enough, 1 patient presented several of the cardinal manifestations of rheumatic activity—namely, joint pains, signs of pericardial effusion and leukocytosis. Notwithstanding these positive features, the diagnosis of active rheumatic fever was not made, perhaps chiefly because of the patient's age (forty-seven years). It must be pointed out that in 3 of the 7 cases the death was directly attributable to the rheumatic heart disease and consequent cardiac decompensation.

Group IV is perhaps the most difficult to interpret. These patients between forty-nine and sixty-two years of age had no history suggestive of rheumatic heart disease, and the physical examination and laboratory studies shed no further light on the possibility of the presence of this disease. Yet on post-mortem examination in each case acute myocarditis with Aschoff bodies was found without anatomic evidence of pericardial or endocardial involvement. In 2 cases these Aschoff bodies were of the active cellular type, indistinguishable from those found in known rheumatic carditis. In the other 2 cases the cellularity was less striking but

sufficient to warrant inclusion as active rheumatic myocarditis.

Whether, in the absence of other stigmas of rheumatic fever, one may term this involvement rheumatic myocarditis is open to the controversy regarding the specificity of the Aschoff lesion.⁸ The myocardial Aschoff lesions in these cases differed in no important respect from those seen in frank rheumatic fever, and it is well known that rheumatic myocarditis may occur as an isolated lesion without valvular or pericardial involvement.^{14, 15} One can only say of these cases that they represented insidious latent acute myocarditis, probably rheumatic in origin and associated in 2 cases with anatomic evidence of decompensation.

SUMMARY AND CONCLUSIONS

In a review of 41 pathologically proved cases of active rheumatic myocarditis the usual clinical manifestations of activity were sufficiently striking in 20 cases to result in a clinically correct diagnosis. Most of these patients were in the first two decades of life. The remaining 21 cases were not diagnosed as active rheumatic disease during the terminal illness, perhaps the most characteristic feature of this group was the age, which averaged fifty-three years and nine months and, except in 5 cases, was over forty years.

In 10 of these 21 patients a previous diagnosis of rheumatic heart disease had been made, and the terminal cardiac decompensation was considered to have been on a mechanical valvular basis without the complicating presence of myocarditis. Possibly owing to lack of awareness of the significance of myocarditis in these older age groups, adequate observations of the PR interval and sedimentation rate were not made in 7 cases. Although in 2 of the 10 cases at no time was there good clinical evidence of rheumatic activity, in several other cases there were single or minor manifestations of active rheumatic disease.

In 7 more of the clinically undiagnosed cases no diagnosis of rheumatic disease had been made in the past, nor was it entertained during the terminal illness. In all but 1 case rheumatic manifestations were singularly absent from this group, and the disease took what may be termed a truly silent form. It is to be noted, however, that in 3 of these patients, although the clinical disease was silent, from the pathological standpoint death was undoubtedly attributable to decompensated acute rheumatic heart disease.

The 4 remaining patients represented subclinical acute rheumatic myocarditis occurring without associated pericardial or endocardial involvement. In these cases it is likely that the myocardial disease was incidental to the actual cause of death and that therefore the diagnosis could hardly have been suspected clinically.

Active rheumatic heart disease with cardiac involvement in older age groups is frequently clinically unsuspected.

The difficulty of clinical recognition of rheumatic activity in older patients can be attributed to several factors in these age groups active carditis assumes in a high percentage of cases an atypical form in which the diagnosis of activity may depend on careful evaluation of isolated rheumatic manifestations, active rheumatic myocarditis as a cause of cardiac failure may be obscured by the presence of complicating diseases, such as hypertension, arteriosclerosis and healed rheumatic valvular disease to which the cardiac decompensation may be reasonably attributed, and, in a certain number of cases, the disease may be entirely silent, rendering clinical recognition difficult if not impossible.

The results indicate that, contrary to the general impression, cardiac decompensation in rheumatic heart disease, even in older persons is frequently the result of activity of the disease.

Syphilis	Penicillin G
Yaws	Penicillin G

*Indications are for oral and parenteral use only The drugs are contraindicated in the infections in which their use is not recommended

†First choice.

‡Second choice.

With what ease can the compound be given?

What will the cost of the agent, or the auxiliary costs of its administration, be to the patient?

All four questions, especially the last two, are important in this day when the costs of medical care are soaring The physician's final decision should

that sulfanilamide and sulfathiazole are not included Either of these drugs may be used when indicated if members of the diazine group of sulfonamides are not available "Sulfaguanidine and other sulfonamides" may be considered to include sulfasuxidine and sulfaphthalidine In all severe cases of

infectious diseases that respond to more than one of these agents, a combination of the two most effective agents should be used

Dosage

It would be repetitious to outline dosage forms for the various compounds listed above. Directions

of vertigo and deafness rarely occur before the fourth day of streptomycin therapy. Patients should be carefully examined each day for symptoms and signs of eighth-nerve involvement, and the drug should be discontinued immediately if such effects are noted. Skin rashes and urticarial reactions similar to those seen in the course of penicillin

regarding dosage are contained in *New and Non-official Remedies*,¹ in which the physician is referred for such information. Also, it can be said that accurate directions for using these drugs are contained in the package inserts of the brands that have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association.

Toxicity

Table 4 outlines the incidence of important toxic reactions noted in the course of sulfonamide therapy. It is obvious from the data presented that sulfadiazine is the least toxic of the four drugs listed. Although comparable figures are not readily available, sulfamerazine and sulfapyridine appear to be somewhat less toxic than sulfadiazine.

Toxic reactions have also been observed after the administration of the antibiotics (Table 5). Initially, it was thought that penicillin was relatively non-toxic. As experience with this antibiotic has increased, however, toxic reactions, especially those of the urticarial and dermal type, have become more frequent. I have witnessed urticarial reactions, which were not only most distressing and painful to the patients but also costly, because the patients were incapacitated for weeks. All varieties from mild erythematous rashes to dermatitis exfoliativa have been noted. Penicillin is not without its danger.

When streptomycin was initially introduced as a therapeutic agent, reactions similar to those following the administration of histamine were frequent. This type of reaction has practically disappeared as the antibiotic substance has become increasingly purified. A most serious and distressing reaction characterized by vertigo and impairment of hearing, however, has been observed in the course of streptomycin therapy. In certain cases the vertigo and deafness appear to be permanent. The symp-

therapy have also been noted after streptomycin administration.

It is my opinion that the time has come to inveigh against the local use of sulfonamides and the antibiotics. There is little evidence that when these agents are used externally as dusting powders, or in creams, lotions or salves, the beneficial effects

outweigh the known risk of sensitizing the patient. Nothing appears to be gained from treating a minor infection locally (when parenteral or oral therapy will achieve the same end) if the patient becomes sensitized to the drug and is thus deprived of its valuable effects, when later he may have an infection in which the agent might be life saving.

CONCLUSION

With a variety of chemotherapeutic and antibiotic agents at the physician's disposal for the treatment of infectious diseases, careful consideration must be given to the selection of the agent that best suits the needs of the patient.

THE OPERATIVE AND POSTOPERATIVE MANAGEMENT OF HYPERTENSIVE PATIENTS UNDERGOING THORACOLUMBAR SYMPATHECTOMY

JERE W LORD, JR, M D,* AND J WILLIAM HINTON, M D †

NEW YORK CITY

THE surgical treatment of hypertension had its origin in the pioneer work of Crile,¹ Adson et al,^{2,3} Page and Heuer,⁴ Peet⁵ and others, but it was not until the brilliant clinical studies of Smithwick,⁶ first published in 1940, that a truly effective operative procedure was available. The extent of the operation described by Smithwick and employed by him for the past eight years included removal of the thoracolumbar chain from the eighth or ninth thoracic ganglion through the first or second lumbar ganglion, along with portions of the greater, lesser and least splanchnic nerves.

Hinton and Lord⁷ reported 152 hypertensive patients operated on by the Smithwick technic between February, 1942, and May, 1945. Follow-up study after six months showed that 53 per cent had a fall in the level of the diastolic blood pressure of 20 points or more—that is, a Group I or Group II result according to Smithwick's classification. Only 30 per cent had diastolic readings below 100. In general the majority of patients selected had suffered from advanced hypertension, essential and malignant, and only a few cases could be classified as falling into the relatively mild or early form, the Group II of Keith, Wagener and Barker.⁸

In the hope of increasing the percentage of patients obtaining significant falls in the postoperative diastolic blood pressure we gradually extended the operation until by December, 1945, the majority underwent an extensive thoracolumbar sympathectomy, which included removal of the sympathetic chain from the third or fourth thoracic through the second or third lumbar segment, along with the entire greater, lesser and least splanchnic nerves. With sufficiently long instruments this procedure can usually be accomplished through an exposure obtained by removal of the tenth rib in toto. This operative approach has recently been described in detail.⁹ A six months' follow-up study of 15 cases in which the extensive sympathectomy had been carried out revealed that 93 per cent of patients had Group I or II diastolic falls and 80 per cent had diastolic blood pressure levels under 100. The hospital mortality in 120 patients undergoing the extensive operation was approximately 6 per cent, all deaths occurring in patients with advanced hypertension.

*Instructor in surgery, Cornell University Medical College, associate surgeon, New York Post-Graduate Hospital, surgeon to outpatients, New York Hospital.

†Clinical professor of surgery, Columbia University College of Physicians and Surgeons, attending surgeon, New York Post-Graduate Hospital, visiting surgeon, Bellevue Hospital, assistant surgeon, New York Post-Graduate Hospital.

As a result of our experience with 400 patients subjected to the two-stage thoracolumbar sympathectomy during the past five years, certain principles of management during the operative and postoperative periods have evolved. The patients on whom the extensive sympathectomy is carried out need every possible adjunct to bring them through without serious complications due either to their disease—that is, coronary occlusion, heart failure, cerebral accident or renal failure—or to a complication of the thoracotomy, such as pleural effusion, pneumothorax, atelectasis or pneumonia.

There are two basic problems to be handled during the operative and early post-operative periods: the maintenance of an adequate blood pressure and thereby avoidance of a marked systolic fall to levels of 90 or lower,—falls that can occur with alarming suddenness especially during and after the second-stage procedure,—and, secondly, the management of the thoracotomy during and after operation.

The maintenance of a relatively stable pressure has been best achieved during the operation by the use of 2 cc of a 1 per cent solution of Neo-Syneprine in 1000 cc of 5 per cent glucose in distilled water administered intravenously and, postoperatively, by the same fluid with 1 cc of Neo-Syneprine per 1000 cc of solution until the systolic blood pressure has been stabilized at 90 or 100 or higher. This may take only a few hours or as long as forty-eight hours. Before the adoption of this method, which was suggested by Dr Milton C Peterson, head of the Department of Anesthesiology of the New York Post-Graduate Hospital, the anesthetist injected intramuscularly or intravenously 2 or 3 minims of Neo-Syneprine when necessary, and the same procedure was used postoperatively. Figures 1 and 2 show the blood-pressure recordings by the anesthetist during the second-stage procedure in 2 cases in which the intermittent method was used in 1 and the continuous technic in the other. In the latter procedure, if the blood pressure falls, the infusion is speeded, and when stabilization has been achieved, it is slowed.

We have found that moderate anemia develops after each stage of the extensive sympathectomy, probably owing to oozing into the extrapleural and intrapleural spaces during the early postoperative period, and for that reason a 500-cc blood transfusion is routinely administered immediately after each stage.

The second major problem in these patients is to obtain hemostasis and to deal with the open thorax

during the operation and to prevent serious hemothorax, pneumothorax, atelectasis and pneumonia postoperatively. Grimson¹⁰ has recently stated his position as follows: a closed anesthetic system is employed, an intratracheal tube being used only occasionally, the pleural cavity is deliberately entered through a partial third-rib and a longer tenth-rib resection, and the chain removed from the stellate ganglion through the first or second lumbar segment, inclusively, followed by the use of a closed-tube suction drainage of the pleural cavity for two or three days. We have also made use of a closed anesthetic system, usually with an intratracheal tube. Recently, we have begun a series without such a tube, and the management in the

Hemostasis is not a simple matter in this procedure, and one of the frequent complications has

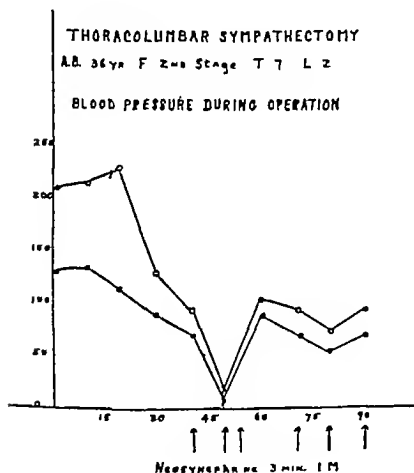

FIGURE 1

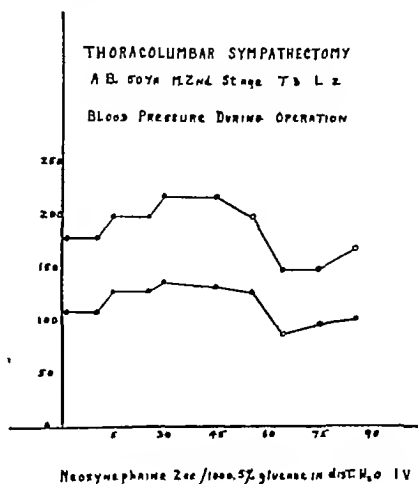

FIGURE 2

been the development of fluid in the chest postoperatively. Grimson¹⁰ has had similar difficulty

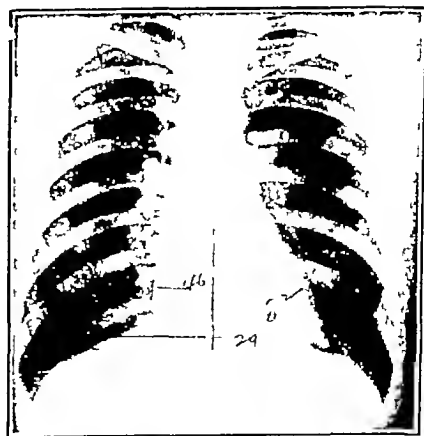

FIGURE 3

hands of experienced anesthetists has been for the most part satisfactory. One point should be emphasized: this extensive sympathectomy should be carried out only when an anesthetist thoroughly familiar with open-chest operative procedures is administering the anesthetic. Although in our technique the parietal pleura is stripped from the chest wall from the diaphragm to the apex of the thorax, it is usually torn to a greater or lesser extent so that air readily passes into the intrapleural space.

Anesthetic agents have included ether, cyclopropane and ethylene, and the indications for and contraindications against these agents may best be found in reports by Phelps and Burdick¹¹ and Burdick, Phelps and Peterson.¹²

by his method of approach. In addition to the clam ~~ligature~~ ligature, there are at one's disposal

temporary pressure on the venous bleeder against the vertebral column, which is often satisfactory, silver clips, oxycel and other hemostatic absorbable agents, bone wax and finally the electrocautery. We have not used the last because of the fear of an explosion in the presence of such potentially dangerous anesthetic agents and the open pleura. Furthermore, the most serious difficulty with hemorrhage is presented by an accidental tear of an intercostal artery high in the chest cavity, such as the third, fourth or fifth.

When hemostasis has been obtained after the removal of the sympathetic chain and suture of the

Other factors of importance in the postoperative management are as follows

Oxygen therapy (by nasal catheter, mask or tent) is used in patients with low preoperative cardiac reserve.

Digitalization of patients preoperatively is effected when evidence of actual or impending congestive heart failure is present, and the drug is continued after operation.

Penicillin in liberal doses is given intramuscularly when the operation has been more difficult than usual or when the pleura has been widely

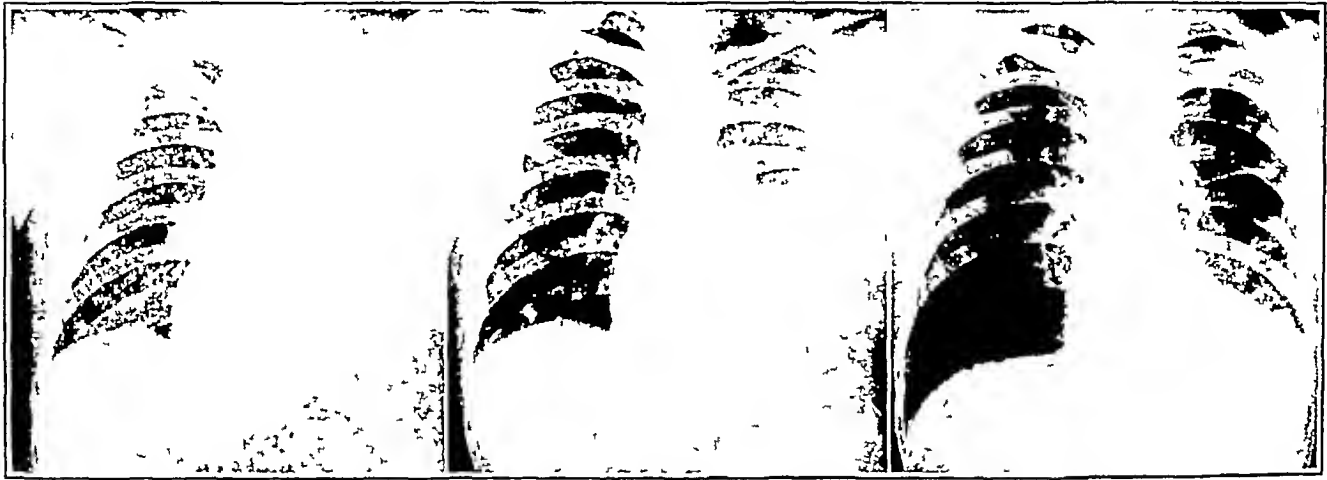

FIGURE 4

diaphragm, the chest wall is closed around a large rubber catheter placed in the pleural space. Air is completely aspirated, the catheter removed, and the skin closed without drainage. During the entire postoperative period, but particularly during the first forty-eight hours, careful, repeated bedside examination of the chest must be made. Signs of fluid or atelectasis (usually due to fluid), or both, are promptly checked by an x-ray film of the chest taken with a portable apparatus, and aspiration with a large (No. 15) needle is carried out. Figure 3 shows the preoperative radiogram of a patient who postoperatively developed signs of fluid on the left side. Figure 4 illustrates radiograms taken on the sixth, tenth and thirteenth postoperative days. Aspiration of 525, 1050 and 900 cc. were made on the seventh, ninth and twelfth days. It is interesting that significant fluid accumulated only after the first operation, and after a second-stage sympathectomy on the right side no fluid developed. In patients with poor cardiac reserve unrecognized pleural effusions (usually hemorrhagic) may be of the gravest significance, and prompt recognition and treatment may be life saving.

torn, with potential trauma to the lung by retraction.

Study of the blood urea nitrogen and the nonprotein nitrogen on the first postoperative day is made to determine to what degree renal function has been disturbed. Occasionally, the blood chemical constituents become greatly elevated after operation, in spite of fairly adequate preoperative renal function, and only by energetic treatment with large amounts of 10 per cent glucose in distilled water and blood transfusions can a serious degree of uremia be avoided. No patient is given physiologic saline solution intravenously during or after either stage of the procedure.

The red-cell count is checked on the first postoperative day, and if an anemia is present in spite of the regular transfusion, further transfusions are administered.

Early ambulation is practiced only after the first-stage sympathectomy. After the second operation patients are allowed up when the blood pressure has been stabilized and when the cerebral and cardiac functions are adequate.

Finally, in a few patients, who preoperatively had had either a stroke or a coronary occlusion, we have cautiously used subcutaneous heparin in Pitkin menstruum postoperatively. Coronary thrombosis is theoretically more likely in a patient who previously has had such an accident and in whom the blood pressure has been reduced sharply from hypertensive to normotensive levels. That this accident does not occur more frequently is remarkable, but the careful use of heparin may be valuable in selected cases. So far, no serious untoward effect has followed the administration of this anticoagulant.

SUMMARY

In the operative and postoperative management of hypertensive patients undergoing extensive thoracolumbar sympathectomy, including the third or fourth thoracic through the second or third lumbar ganglia, certain factors are of value: the use of 2 cc of a 1 per cent solution of Neo-Synephrine in the intravenous fluid given during and after each operative stage, and closure of the chest incision without drainage, followed by careful postoperative check-up by physical examination and portable x-ray films.

The types of anesthetic agent, the use of oxygen, digitalis, penicillin, studies of the blood chemistry and red-cell count, early ambulation and heparinization are discussed.

PNEUMOPERITONEUM FOLLOWING GASTROSCOPY APPARENTLY WITHOUT PERFORATION

Report of a Case

DONALD T. CHAMBERLIN, M.D.*

BOSTON

PNEUMOPERITONEUM following the usually benign procedure of gastroscopy is so startling when it occurs that an additional report is believed to be of value. There have been only three previous reports of this condition. In the first, presented by Schiff¹ in 1941, the only finding was subdiaphragmatic air at x-ray examination four days after the gastroscopy. In the case reported by Schindler² in 1945, laparotomy was performed three hours after the onset of the pneumoperitoneum, methylene blue was injected into the gastric lumen, and oxygen blown into the stomach under a pressure of 60 pounds, but no perforation was found. Berk³ reported the third case, in which, again, no perforation could be found at laparotomy. Schindler postulated a slit-like perforation of the stomach that promptly healed, although no trace of it was present.

The following case† differs from those previously reported in that a large gastric ulcer was present (Fig. 1).

E. L., a 42-year-old truck driver, was admitted to the hospital on March 5, 1947, for gastroscopy, which was unsatisfactory. The instrument passed with ease but the stomach was difficult to inflate and contained considerable mucus. An ulceration was momentarily visualized, but not sufficiently to make a diagnosis. Because of the large amount of mucus the instrument was removed. The patient belched copiously but did not complain of pain. An Ewald tube was passed and an attempt was made to aspirate the mucus. Nothing was obtained. The gastroscope was reintroduced easily. The stomach did not inflate to any degree and the examination was terminated. The abdomen was distended but the patient could not belch any air. The distention continued all day.

Physical examination showed the abdomen to be tight and tympanic. The liver dullness had disappeared. Both leaves of the diaphragm were high. Examination of the scrotum revealed emphysema. The patient was not in shock and had no pain, but he became dizzy. If his position was changed the temperature, pulse and respirations were normal.

†Reported through the courtesy of Dr. Leo Lynch of Malden, Massachusetts.

*Assistant in medicine, Harvard Medical School; research assistant Thorndike Memorial Laboratory Boston City Hospital; physician Malden Hospital.

Examination of the blood disclosed a white-cell count of 20,000. A plain film of the abdomen demonstrated a marked pneumoperitoneum (Fig. 2).

The diagnosis was pneumoperitoneum without apparent perforation.

Since the only complaint throughout the day was a feeling of fullness, the patient was allowed to continue his ulcer management, which he did without distress or nausea. However, during the early evening, the temperature, which had been normal all day, began to rise, and it was deemed in-

On March 8 the course was uneventful. The emphysema was still present in the carotid sheath and suprapubically.

Pathological examination by Dr. M. V. MacKenzie revealed a roughly triangular piece of stomach wall measuring 5.0 by 3.0 by 1.5 cm. The mucosa was velvety, edematous and grayish white. In the center there was a punched-out ulcer crater measuring 1.2 by 2 cm. and extending approximately 0.5 cm. below the surface. The edges were rolled, and the base contained adherent, fibrous tags of tissue. The serosal surface was spongy and edematous, with adherent fibrous tags of tissue and many areas of hemorrhage. Section revealed a homogeneous, edematous, pink-gray surface with many flecks of necrotic tissue and areas of hemorrhage. The ulceration had extended through the muscularis but had not, apparently, penetrated the serosa. The presence of dilated lymphatic vessels (including the perineural vessels) suggested a possible pathway for the air.

The gross diagnosis was chronic penetrating gastric ulcer, with necrosis and marked edema of the surrounding tissue.

The patient experienced no abdominal pain, beyond the usual discomfort associated with dis-

FIGURE 1 Roentgenogram Showing Large Gastric Ulcer on the Lesser Curvature

advisable to continue the policy of noninterference. Accordingly, exploration was decided on.

At operation* under spinal anesthesia a high left rectus muscle incision was made. The peritoneum was under such marked tension that it was difficult to grasp it with forceps. Opening released a gust of air much more violent than that encountered in the ordinary case of perforated ulcer. The abdomen collapsed. There was no intestinal distention, no free fluid and no fibrin. The stomach was thickened, and there were emphysematous blebs along the lesser curvature and extending into the fundus. There was no perforation on the anterior gastric surface. The lesser omental sac was opened through the omentum and the posterior wall inspected, but there was no perforation. Marked retroperitoneal emphysema was observed over the aorta. Since it seemed that there must be a microscopic perforation—probably retroperitoneal—and since the ulcer was not definitely palpable, the stomach was opened. An ulcer crater, almost 2 cm. in diameter, was discovered on the posterior wall, extending onto the lesser curvature at its mid-portion. The lesser omentum was dissected from the lesser curvature, and the right and left gastric arteries were ligated. A wedge resection was done after the method of Walton. The mucous membrane was approximated with silk. Gastroenterostomy was not performed. Rents in the greater and lesser omentum were repaired. The abdomen was closed in layers without drainage.

*Performed by Dr. W. J. Reynolds.

FIGURE 2 Roentgenogram of Abdomen Showing Marked Pneumoperitoneum

tention, at any time during the gastroscopic examination. The scrotal emphysema was noted late in the day after gastroscopy, but the carotid sheath and suprapubic emphysema did not appear until the following morning. In this case, the Walton resection of the ulcer was justified because of the interstitial emphysema of the wall of the stomach. It is doubtful if the sutures of a subtotal gastrectomy would have held in this tissue.

The possible anatomic route for the spread of the emphysema is suggested in the description of the microscopical appearance of the tissue taken from the ulcer. The perineural lymphatic vessels were dilated more than is seen in a section through an ordinary gastric ulcer. The interstitial emphysema of the stomach wall may be explained on this basis. The free air in the peritoneal cavity had probably been diffused through the very thin base of the ulcer. The peripheral emphysema of the scrotum along the fascial planes, in the neck and in the abdominal wall may have been due to the passage of air along the lymphatic and blood vessels of the stomach wall.

In 2 of the previously reported cases,^{2,3} as in the case reported above, laparotomy was performed soon after the occurrence of the pneumoperitoneum. Because of the rarity of the complication, laparotomy was justified, to find and repair any possible perforation. In the future, however, if I encounter a similar case, I shall not be so anxious to have the

patient explored, but shall at once put a needle of large caliber into the abdomen, with the patient lying on his back, and attempt to remove the free air in the peritoneum by this means, waiting for further signs of perforation before asking for a laparotomy.

SUMMARY

A case of pneumoperitoneum following gastroscopy is reported.

A brief review of the literature is presented.

A suggestion regarding the management of such cases is made.

MEDICAL PROGRESS

INFLUENZA*

JOHN H. DINGLE, M.D.†

CLEVELAND, OHIO

INFLUENZA is an old and well established disease that has appeared in epidemics and pandemics since before the seventeenth century. Despite its long history, however, the cause or causes of both epidemic and pandemic influenza remained unknown until fifteen years ago. Since then, remarkable progress in the methods of study and knowledge of epidemic influenza has taken place. Epidemic influenza has been established as a virus infection caused by one or the other of two very similar agents, methods have been devised that have permitted chemical and physical characterization of the viruses, re-evaluation of the clinical and epidemiologic nature of influenza has been made possible on the basis of a simple and specific laboratory diagnostic test, and, finally, a vaccine that holds some promise for the ultimate prevention and control of the disease has been developed. The cause of pandemic influenza is still unknown. The following discussion is an attempt to summarize recent progress, with no intent exhaustively to review the literature.

CAUSE OF EPIDEMIC INFLUENZA

In 1933 Smith, Andrewes and Laird,¹ in England, accomplished for the first time the transmission of infection from a human case of influenza to an animal, the ferret. They determined that the agent was a virus that, immunologically, was causally related to the human disease. In the following year, Francis² confirmed this observation in the United States and isolated, from a specimen obtained in Puerto Rico, a similar strain, termed "PR8," which has been widely used for investigative purposes in this country. It soon became apparent, however, that strains of this immunologic character were not responsible for all the outbreaks of acute respiratory disease resembling influenza clinically and epidemiologically. In 1940 Francis³ isolated in ferrets a new strain of influenza virus, termed the "Lee" strain, which was immunologically distinct from the former strains. A similar strain was isolated in the same year by Magill.⁴ The two types of virus are now known as influenza virus A, of which the PR8 strain is an example, and influenza virus B, typified by the Lee strain.⁵

Thus, two similar but immunologically distinct viruses cause human influenza. Comparable situa-

tention, at any time during the gastroscopic examination. The scrotal emphysema was noted late in the day after gastroscopy, but the carotid sheath and suprapubic emphysema did not appear until the following morning. In this case, the Walton resection of the ulcer was justified because of the interstitial emphysema of the wall of the stomach. It is doubtful if the sutures of a subtotal gastrectomy would have held in this tissue.

virus particles. Such data on diameter and water content of the influenza viruses are given in Table 1.

In addition to the methods of study described above, it is now possible to photograph the virus particles themselves by means of the electron microscope and to make direct observations of the size and shape of the images on photographic plates or prints. Direct measurement of the diameter of influenza-virus particles shows moderate variation in size, with an average diameter of approximately 100 millimicrons, which is about one tenth the diameter of the smallest bacteria.

The human influenza viruses A and B and the swine influenza virus are indistinguishable under the electron microscope. Purified preparations appear

molecular in nature but have a behavior and structure indicative of organized cell-like bodies surrounded by a semipermeable limiting membrane.²¹

Biologic Characteristics

Since the adaptation of the influenza viruses to the mouse and embryonated egg, the biologic properties of the agents have been extensively studied

FIGURE 1 Electron Micrograph of Influenza Virus A by Usual Technique ($\times 46,000$)

to consist of rounded or bean-shaped, cell-like particles when examined by the usual technique, which gives a two-dimensional image (Fig 1). Recently, Williams and Wyckoff²² described a "shadow" technique, which introduces a three-dimensional appearance, brought about by the deposition at an angle of a thin layer of vaporized metal over the dried film of virus. The "shadow" is that area, behind the particle, on which no metal is deposited. Viewed by this technique, the influenza-virus particle appears as a more or less spherical body, varying somewhat in size and shape (Fig 2).

Although the full significance of these observations has not yet been determined, there is increasing evidence that the influenza viruses are not

FIGURE 2 Electron Micrograph of Influenza Virus A by Shadow Technique Employing Metallic Chromium ($\times 50,000$)

The infectivity for mice and eggs provided a means of quantitating the amount of virus in a given preparation. This activity, in turn, was found to be neutralized by specific antiserums, which permitted comparison of the antigenic composition of different strains of virus and also serologic diagnosis of human infection. Complement fixation was similarly employed. The two techniques of neutralization and complement fixation have now been largely replaced by a simpler and less expensive test *in vitro*. In 1941 Hirst,²³ and independently McClelland and Hare,²⁴ observed that chicken red cells were agglutinated by allantoic fluid containing influenza virus, and that such agglutination could be inhibited by immune serum. On the basis of this property of the virus, an *in vitro* test that permits the rapid determination of the virus content of an infected fluid or of the amount of antibody in a serum was developed.^{25, 26} Further study of the mechanism of the reaction revealed that the virus was adsorbed to the erythrocytes prior to their agglutination and that, under proper condi-

tions, it could be concentrated by elution from the cells^{37, 38} The discovery and application of this biologic property constitute a major contribution to the academic and practical study of influenza. The reaction has been utilized for fundamental investigations of the characteristics of strains of virus as they are isolated from human patients and adapted to other tissues. It has been of value for concentration and partial purification in the preparation of vaccines and as a preliminary step before further purification by ultracentrifugation. Finally, it has provided the basis for a simple method of con-

FIGURE 3 *Electron Micrograph of Influenza-Virus Vaccine*
($\times 35,000$)

firming the diagnosis of influenza in the laboratory.

Preparations of concentrated and partially purified influenza viruses have provided laboratory investigators with more highly refined reagents for study of the biologic characteristics of the agent than were previously available. Such materials have been utilized not only for the evaluation of serologic methods for diagnosis but also for the study of the immunizing capacity of the viruses in man and in animals³⁹⁻⁴⁸ The present influenza-virus vaccine is one of the results of this work (Fig 3). A toxic action, apparently inherent in certain strains of living influenza virus, has also been demonstrated in both crude and partially purified preparations^{48a} The toxic activity is destroyed when the virus is killed by heat or formalin.

An additional biologic characteristic of influenza viruses that warrants consideration here is the considerable variation in the antigenic composition of individual strains of influenza virus A. For example, the strains isolated from patients during

the late winter and spring of 1946-1947 differed antigenically from the PR8 strain to such an extent that serums drawn during the acute and convalescent phases showed no change in antibody titer when tested with the PR8 strain, and yet showed a definite rise in titer to the newly isolated homologous strain^{49, 50} Such changes in the characteristics of influenza virus A, which may be due to true mutation, are of great academic interest to those seeking an understanding of the biologic behavior of influenza⁵¹ They are perhaps of even greater practical importance to those concerned with the laboratory diagnosis of influenza and the preparation of influenza-virus vaccines, as indicated below.

CLINICAL CHARACTERISTICS

Influenza is generally considered as a dramatic and acute respiratory disease^{52, 53} The onset is often described as sudden and abrupt—so much so that the patient may give the exact hour, prior to which he felt well and after which he was ill. Occasionally fainting or collapse may be the first sign of infection. The early complaints are those of headache, pain in the eyeballs and on movements of the eyes, pain in the back and muscles, malaise, fatigue, weakness or dizziness, chilliness and feverishness. Respiratory symptoms, such as coryza, husky voice, sore throat and dry cough, may or may not be prominent and usually appear after the more marked constitutional symptoms. On physical examination, the patient appears to be acutely ill and markedly prostrated. The temperature is elevated, and there is a relative bradycardia. The face is flushed. Cyanosis may be present, and the skin is occasionally of a peculiar purplish or heliotropic hue. Conjunctivitis is prominent, and the throat appears injected but dry, with a "granular" appearance. The remainder of the physical examination is noncontributory, although occasionally moist rales and rhonchi may be heard in the chest. Leukopenia is the rule.

The course of the illness is characterized by a brisk fever, lasting three to five days and often diphasic. Defervescence is accompanied and followed by marked asthenia. Complications are infrequent, apart from pandemics, and vary in type from pneumonia to sinusitis. The pneumonia is occasionally caused by the virus but is usually due to a secondary or simultaneous bacterial invasion with such organisms as pneumococci, beta-hemolytic streptococci, staphylococci and influenza bacilli. Such an infection may be fulminating and rapidly fatal.

This is essentially the "textbook picture" and is drawn, to a large extent, from observations made during the catastrophic pandemics of influenza. Since 1920, particularly since isolation of the influenza viruses permitted laboratory confirmation of the clinical diagnosis, the clinical picture has

been shown to be much more variable and less striking. During the period of an influenza epidemic, the majority of patients seeking medical care for respiratory illness show laboratory evidence of infection with the influenza virus, almost regardless of the clinical characteristics presented. In non-influenza periods, the reverse is true. If one compares the frequency of symptoms and signs in two such groups of patients, selected on a laboratory basis as "influenza" and "noninfluenza respiratory disease," it will be found that the former group more nearly approaches the textbook picture. In the epidemic of influenza A during the winter of 1943-1944, for example, it was observed that a sudden onset occurred in 35 per cent of cases of influenza in contrast to 19 per cent of the non-influenza cases. The values were 94 and 82 per cent for feverishness, 70 and 53 per cent for malaise, 42 and 69 per cent for sore throat and 84 and 85 per cent for cough, respectively. On physical examination, 32 per cent of patients with influenza were considered to be moderately or severely ill, whereas only 10 per cent of the "noninfluenza" cases were so classified. The signs of flushed face were found in 45 and 22 per cent, of injected conjunctiva in 46 and 21 per cent, of pharyngeal injection in 6 and 13 per cent, and of rales in the lungs in 11 and 6 per cent, respectively.¹¹⁻¹⁶ It is thus apparent that cases of influenza, as a group, present a clinical syndrome that differs significantly from that of noninfluenza respiratory disease. The same symptoms and signs, however, occur frequently enough in patients of both groups to prevent a definitive clinical diagnosis in a single patient without laboratory confirmation.

In epidemic periods, moreover, inapparent or subclinical infection with the influenza virus, detectable serologically, occurs two or three times more frequently than that of clinically recognizable influenza.¹⁷⁻¹⁹ Influenza must therefore be considered a respiratory disease that varies in its clinical nature from a symptomless infection to a severe and at times rapidly fatal disease.

There is now no doubt that sporadic infection with either influenza virus A or B may occur in nonepidemic periods, as proved both serologically and by isolation of the virus.²⁰⁻²² Such cases, however, are almost invariably detected by laboratory methods. The clinical diagnosis of influenza A or B in nonepidemic periods is usually in error.

DIAGNOSIS

Since the clinical picture in the individual patient, or in the sporadic case, is not a reliable indication of the occurrence of influenza, the question naturally arises regarding the means by which influenza A or B can be diagnosed. Generally, such a diagnosis can be based most reliably on a combination of clinical and epidemiologic data. The occurrence of an unusual number of cases of respiratory illness,

many of which exhibit the clinical features associated with influenza, is strong presumptive evidence in favor of the diagnosis of influenza. Confirmation of the diagnosis, however, must be made in the laboratory. Two general methods are available: isolation of the virus and determination of the antibody titers of the patients' sera.

Isolation of the virus is the more difficult and expensive of the two methods. Satisfactory specimens for this purpose may be obtained by washing the patient's nose and throat, or having him gargle, with nutrient broth or buffered saline solution. Such specimens should be collected prior to the fourth day of illness, since the virus is rarely found after that time. The virus may then be sought by the intranasal inoculation of ferrets or by the inoculation of embryonated eggs.²³⁻²⁵ When the latter procedure is employed, bacterial infection may be prevented by filtration of the washings or by the addition of sulfonamides and antibiotic agents.²⁶⁻²⁸ The presence of the virus in ferrets is indicated by fever and injection of the nasal turbinates, and after passage to additional ferrets, by the production of pneumonic lesions. In eggs, the virus may be detected by its ability to agglutinate erythrocytes. Once established in either ferrets or eggs, the strain may be identified as influenza virus A or B by immunologic methods employing known antiserum for each of the two types of virus.

Diagnosis by determination of the antibody titers of the patients' sera requires the collection of two specimens of serum, one obtained during the acute phase of the disease, preferably before the fifth day, and the other, a convalescent specimen, obtained about the fourteenth day of disease or thereafter. These sera are then titrated for antibody content with a known strain of influenza virus A and one of virus B. Such determinations may be performed by measuring the capacity of the sera to inhibit agglutination of chicken erythrocytes by the virus (agglutinin-inhibition test), by complement fixation or by titrating the capacity of the sera to prevent the infection of mice or eggs by known quantities of virus (neutralization test). The simplest of these determinations and the one most widely used today is the agglutinin-inhibition test. A fourfold or greater increase in antibody titer for one or the other of the two viruses, between sera drawn during the acute and convalescent phases, is generally accepted as indicative of specific infection with that type of influenza virus. It is important that both sera be examined on the same day with the same set of reagents to avoid differences in titer due to technical variations in the tests. It is also essential that this test be carried out with the strain causing the current epidemic, when that strain is available.²⁹⁻³⁰

Neither of these laboratory procedures will permit more than a retrospective or confirmatory diagnosis in an individual patient because of the time required

for their performance. With unusually good fortune, the virus may be isolated in eggs and identified within forty-eight to seventy-two hours from the time of collection of the washing. More frequently from one to three weeks is necessary. Similarly, serologic diagnosis cannot be made for at least nine to fourteen days after the onset of illness, because of the time required for antibody formation in the patient. The development of a rapid diagnostic test would be a major contribution to the problem of influenza.

TREATMENT

There is no specific agent available for the treatment of influenza. As with other virus diseases, specific antiserum does not alter the course of the disease once the infection is sufficiently established to be recognized as a clinical illness. The sulfonamide drugs and penicillin have no effect on either the virus or the clinical disease. A great deal of time and effort has been and is being spent in the search for chemical or antibiotic agents that might be active against viruses without damaging the host cells — a requirement that must be met before successful therapy will be attained. Although the results with nitroakridin⁶⁹ and with various complex polysaccharides^{69a, 69b} appear to be hopeful, no agent has yet been found that can be recommended for clinical use.

The treatment of uncomplicated influenza thus consists of supportive measures, such as bed rest, antipyretics and sedation as indicated, and fluids sufficient to give an output of at least 1000 to 1500 cc per day. Steam inhalations frequently relieve to a considerable extent the symptoms of irritation of the respiratory tract. The bacterial complications of influenza should be treated with sulfonamides or antibiotic agents in the same way that similar bacterial infections are treated in the absence of influenza. Penicillin is now the agent of choice when the causative organism is a beta-hemolytic streptococcus, a pneumococcus or a staphylococcus. Streptomycin may be effective when the organism is a gram-negative bacillus, such as *Haemophilus influenzae*.⁷⁰

At present the routine use of sulfonamides or antibiotics for the prevention of complications appears to be neither necessary nor desirable, since their administration is not without the hazards of sensitization and toxic reactions. In the epidemics of influenza that have occurred since 1920, the incidence of complications has been extremely low, and the mortality even lower. Prophylactic use of these agents may be of value, however, in patients who are most severely ill and in those who are harboring pathogenic bacteria in the upper respiratory passages. In the 1940-1941 epidemic of influenza A, for example, *Staphylococcus aureus* was found with unusual frequency in throat cultures of patients with influenza, and pneumonia due to this

organism was an outstanding feature of the epidemic.^{19, 20} It seems reasonable to expect that these antibacterial drugs will be of prophylactic as well as therapeutic value in the event of another pandemic of influenza.

PERIODIC RECURRENCE OF EPIDEMIC INFLUENZA

For a number of years, the periodic recurrence of influenza has been of considerable interest to biostatisticians, epidemiologists and others concerned with the cyclic occurrence of infectious disease and the reasons for such behavior. These studies, generally considered to be of academic interest only, assumed practical importance during the war. Predictions of the occurrence of epidemics were sought not only to prepare for the hospitalization and care of the casualties from influenza but also to indicate the most effective time for administration of the relatively limited supply of influenza-virus vaccine. If it were possible reliably to predict the recurrence of influenza A or B, indiscriminate use of the vaccine could be avoided.

Such predictions, on a world-wide basis, were not possible then and are not now, because the usual epidemics of influenza do not occur simultaneously throughout the world.⁷¹ In the United States, however, a more consistent pattern of recurrence seems to obtain. In the brief period since the identification of the two influenza viruses, influenza A has occurred at an interval of two to three years and influenza B at an interval of four to six years, as demonstrated serologically and by isolation of the viruses.^{7, 58, 72, 73} These cycles of recurrence for influenza A and B, projected back to 1920, will account for each year in which there has been an excess mortality from pneumonia and influenza — a criterion that Collins²¹ has employed to indicate the occurrence of epidemic influenza. If the cycles are correctly defined, twelve of the eighteen epidemics of influenza since the pandemic of 1918 and 1919 have been due to influenza virus A. Seven of the twelve epidemics have been separated by two-year intervals, and the remainder by three-year intervals. Similarly, influenza B has recurred at four-year intervals three times and at five-year to six-year intervals on two occasions.

It thus appears possible to predict the probability of recurrence of influenza A or B in the United States within the definite time limits of two to three years and four to six years, respectively. Further observations in the coming years are necessary to test the validity of this theory, particularly in view of the apparent capacity of influenza virus A to undergo what might be termed "antigenic mutation." If the behavior proves to be constant, there appears to be little reason to immunize with influenza virus A in the year following an epidemic of influenza A, or with virus B in the three years following an outbreak of influenza B.

INFLUENZA-VIRUS VACCINE

Prior to the war, several extensive studies of the prophylactic effect of influenza-virus vaccines were carried out.⁷⁴⁻⁷⁷ The vaccines employed consisted of emulsions of chick-embryo tissue containing relatively low concentrations of influenza virus A. The results obtained with this vaccine indicated in general a reduction in attack rate of approximately 50 per cent in the immunized population groups.

With the development of the improved methods for growing and concentrating the viruses and the advent of war, added impetus was given to the evaluation of immunization procedures. The Commission on Influenza^{78, 79} observed approximately 70 per cent protection during the 1943 epidemic of influenza A in immunized, as contrasted with control groups observed at California, Iowa, Michigan, Minnesota and New York. In the 1945-1946 outbreak of influenza B, the results suggested even better prevention.^{80, 79} During the recent 1946-1947 outbreak of influenza A, however, vaccinated and control groups showed no significant difference in the occurrence of influenza,^{40, 80, 79a} indicating the failure of the vaccine to induce immunity. In retrospect, it appears probable that this failure was due to the antigenic differences between the strain of virus responsible for the epidemic and the strains incorporated in the vaccine employed.^{40, 80, 79a}

Although there is no reason to discount the former successful trials of immunization because of last year's failure, it is apparent that further investigation is necessary before influenza-virus vaccine is accepted as an established agent for immunization. It is possible that antigenic variations in the influenza viruses will prevent successful immunization unless new strains can be isolated from sporadic cases in advance of the epidemic and incorporated in the vaccine. There is also reason to believe that in the vaccine. There is also reason to believe that parenteral inoculation of killed virus may not be the final answer to the prevention of influenza. Whereas such inoculation, in the majority of cases, will elevate the antibody level in the blood, the exact relation between humoral antibodies and resistance to infection is still undetermined. The portal of entry of the virus is the respiratory tract, and the possibilities of local tissue immunization, which Burnet⁸¹ has emphasized, have not been exhausted.⁸¹ In this regard, the experiments of McLean, Beard and Beard⁴⁶ with swine influenza, which in its uncomplicated form closely resembles human influenza clinically and immunologically, are pertinent. Parenteral administration of formalin-inactivated, purified swine influenza virus conferred resistance on 37 per cent of the animals to challenge infection with active virus, whereas exposure to active virus, regardless of the severity of resulting disease, rendered 82 per cent of the animals immune to subsequent infection. Such a difference is suggestive of a mechanism of immunity other than that

induced by the parenteral inoculation of virus. It is entirely possible that the virus-inactivating substances present in nasal secretions^{82, 83} and tissue alterations in the respiratory tract following infection⁸⁴⁻⁸⁶ are important factors in the mechanism of resistance.

PANDEMIC INFLUENZA

The cause of the disastrous world-wide pandemics of influenza is not known, nor is there any sound basis for predicting when another pandemic may occur. Certainly, the epidemiologic behavior of pandemic influenza has been quite different from that of the more frequent outbreaks of influenza A or B, and the incidence of severe bacterial complications has been much higher. It seems probable that the primary inciting agent in pandemics is a virus, but whether that agent is a particularly virulent variant of influenza virus A or B or an entirely new virus, or both viruses A and B acting simultaneously, is an open question. It is also possible that pandemics result from the synergistic action of an influenza virus and one or more of the pathogenic bacteria of the respiratory tract. Whatever the cause, the discovery of the sulfonamide drugs and the antibiotic agents has provided more effective weapons for combating the deadly aspects of a pandemic — the secondary bacterial complications — than were ever available in the past.

The electron micrographs reproduced above were obtained through the kindness of D. G. Sharp, Ph.D. of Duke University School of Medicine, and J. W. Beard, M.D.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Stated Meeting, October 1, 1947

A STATED meeting of the Council was called to order by the president, Dr Edward P Bagg, Hampden, on Wednesday, October 1, 1947, at 10.30 a m in John Ware Hall, 8 Fenway, Boston. Two hundred and twenty-nine councilors (Appendix No 1) were present.

After opening the meeting the President read the following obituaries

WALTER PRENTICE BOWERS — Since the May meeting of the Council the life of Walter Prentice Bowers which lacked but eight years of spanning a century, came to a peaceful end. Perhaps he will be remembered best as an outstanding example of the practitioner of medicine. For his accomplishments as such at the age of eighty he was granted an honorary degree of Master of Arts by Harvard University his Alma Mater in medicine.

Clinton Massachusetts more specifically will remember Walter Bowers as the home town boy, son of the Baptist minister who made good entirely on his merits as a beloved physician, and as a leading citizen who among other civic activities founded the Clinton Hospital and served as president for half a century.

He served his state as well on the Board of Registration in Medicine, acting as secretary for nearly a decade. He did much to maintain and improve standards of medical practice in this capacity.

To Dr Bowers the Massachusetts Medical Society must stand forever in debt because of his vision in advocating the purchase by the Society of the *Boston Medical and Surgical Journal* and for his able management in bringing that valued publication out of the shadow of bankruptcy to a solvent state and to a position of national recognition. In addition, he, the perennial councilor guided the Massachusetts Medical Society with distinction as president from 1912 to 1914 and he never once lost sight of its best interests.

Only his close friends knew of Uncle Walter's substantial though unheralded kind deeds to students and to young professional colleagues but one and all must agree that Emerson might have had Walter Prentice Bowers in mind when he wrote, "The world is upheld by the verities of good men, they make the earth wholesome."

ROBERT NASON NYE — Today the *New England Journal of Medicine* enjoys a preferred status among students of medicine old and young no matter where the healing art has called them in prospect, in practice or in teaching and research, just as in wartime the accurate and authoritative information bound within the modest white covers followed them everywhere from Arctic snows to steaming tropical jungles. Already we have dealt with the passing in the fullness of years of Walter Bowers the inspired editor who laid the groundwork for this notable achievement.

By a tragic coincidence the sad duty devolves upon us to record at this same session the untimely completion of such mortal data as concern the life of Robert Nason Nye who brought to fruition the fondest dreams of his predecessor in the management of the *Journal*.

Of Robert Frost, our *New England poet* a wise critic wrote that, "Truth has been his central passion." The

poet himself declared that, "The fact is the sweetest dream that labor knows furthermore, in a philosophic mood he continued

And were an epitaph to be my story
I'd have a short one of my own
I would have written of me on my stone
I had a lover's quarrel with the world

That is to say he held himself free to question the world, even to criticize but always with understanding and real feeling.

Such a brief summary would describe the spirit of Robert Nye as accurately as that of Robert Frost. But in addition, Bob Nye graduated from Harvard *cum laude* whereas the other Bnh left at the end of two years. And though the poet managed the rock bound farm after a fashion the pathologist, turned editor, evinced to positive aptitude for business management that credit balances have resulted for our publication. Bnh men of letters united their vocations and their vocations as their two eyes made one in sight. Both were sensitive observers of the world about them whether the phenomena were natural or human.

Only yesterday it seems Bob came seeking a sufficient advance to cover the purchase of next year's paper and for confirmation of the accuracy of an editorial. Today his chair stands vacant his blue pencil lying where it left his hand.

The world of medical publication will miss the exemplary work of the perfectionist, Dr Robert Nye. Likewise will the Massachusetts Medical Society feel the absence of his sound advice and cheerful co-operation in special committee work. But we who have known him and worked with him will miss still more the genial personality. We who have taken Bnh Nye for granted for so long confess our deep dismay in the contemplation of replacement of this able man who met his ultimate deadline on the tenth of September.

The inspiration of lives such as these must persist and spur us on to keep our standards high and relations with our fellows human. May the "Peace that passeth all understanding" reward their several labors.

At the request of the President, the Council stood for one minute in silent tribute to the memory of Dr Bowers and Dr Nye.

The Secretary presented the record of the annual meeting of the Council, held on May 19, 1947, as published in the *New England Journal of Medicine*, issue of August 21, 1947, and moved its acceptance. The motion was seconded by Dr Harold G Giddings, Middlesex South, and it was so ordered by vote of the Council.

APPOINTMENTS

The President then announced the following interim appointments

To the Committee to Study Special Services

Dr Elmer S Bagnall Essex North and Mr Reginald F Cahalan representing Massachusetts Hospital Service

*Untermeyer, L. Introduction and commentary. *Pocket Book of Robert Frost's Poems*. 263 pp. New York: Pocket Books, Inc., 1946. P 12

Dr Arthur W Allen, Suffolk, and Dr Charles G Hayden, Norfolk, representing Massachusetts Medical Service
 Mr Frank E Wing, Rev Donald A McGowan and Dr Charles F Wilinsky, Suffolk, representing Massachusetts Hospital Association
 Dr Merrill C Sosman, Suffolk, and Dr Hugh F Hare, Middlesex South, representing the specialty of radiology
 Dr G Kenneth Mallory, Norfolk, and Dr Donald A Nickerson, Middlesex East, representing the specialty of pathology
 Dr Urban H Eversole, Norfolk, and Dr Sidney C Wiggin, Suffolk, representing the specialty of anesthesiology
 Dr Leland S McKittrick, Suffolk, chairman, and Dr Joseph Garland, Suffolk, secretary, representing the Massachusetts Medical Society

To the Subcommittee on National Legislation
 Dr Charles G Hayden, Norfolk

To the Committee on Postgraduate Medical Education
 Dr Leo F King, Middlesex North
 Dr Claude E Welch, Suffolk.

To the Committee on New England Postgraduate Assembly
 Dr Joseph Garland, Suffolk

To the Committee to Survey Salaries
 Dr Albert A Hornor, Suffolk

As Advisory Council to the Woman's Auxiliary of the Massachusetts Medical Society
 Dr John F Conlin, Suffolk, chairman
 Dr Milton J Quinn, Middlesex East
 Dr David L Belding, Norfolk South

To the Committee on School Health
 Dr Kenneth L MacLachlan, Middlesex East

*Delegates (June 1, 1947, to June 1, 1949)**

DELEGATES	ALTERNATES
Dr Charles J Kickham, Norfolk	Dr John Fallon, Worcester
Dr Leland S McKittrick, Suffolk	Dr Harold R Kurth, Essex North
Dr Patrick J Sullivan, Berkshire	Dr Allen G Rice, Hampden

Delegate to Annual Meeting of the Vermont State Medical Society
 Dr Wilfred T Hood, Middlesex South

To Annual Meeting of House of Delegates of the American Medical Association, June, 1947
 Dr Allen G Rice, Hampden

To the Council
 Dr Walter L Sargent, Norfolk South, to replace Dr Reardon, *ex-officio*
 Dr Robert S Palmer, Norfolk, to replace Dr Kickham, *ex-officio*
 Dr Carl F Maraldi, Suffolk, to replace Dr Garland, *ex-officio*
 Dr Leland S McKittrick, Suffolk, to replace Dr Nye, deceased

Delegates to Veterans Administration Home Town Medical Care Program, November, 1947
 Dr Humphrey L McCarthy, Norfolk
 Dr James K Bragger, Norfolk

To the Veterans Administration Board of Review
 Dr Humphrey L McCarthy, Norfolk
 Dr James K Bragger, Norfolk
 Dr Timothy F P Lyons, Norfolk
 Dr Edward P Bagg, Hampden
 Dr Joseph Garland, Suffolk

The President asked for confirmation of these appointments, and it was so ordered by vote of the Council

REPORTS OF COMMITTEES

Executive Committee — Dr Joseph Garland, Suffolk, *Secretary*

The Secretary submitted the report (Appendix No 2) as distributed in mimeographed form and moved its acceptance. It was so ordered by vote of the Council

Committee on Membership — Dr Peirce H Leavitt, Plymouth, *Chairman*

This report had been distributed to the Executive Committee in mimeographed form and accepted by that committee with one amendment, as set forth in the report of the Executive Committee. Dr Leavitt moved the acceptance of the report, the motion was seconded and it was so ordered by vote of the Council

Committee on Public Relations — Dr Harold R Kurth, Essex North, *Secretary*

This report (Appendix No 3) was submitted by the President, who pointed out that the chief subject of contention in the report had to do with the Blue Shield policyholders' status as regards income. Dr H M Kemp, Franklin, had indicated that little attempt was being made by Blue Shield to determine accurately an applicant's yearly income. Often a physician, aware that his patient's income is above the accepted \$3000, is entitled to make extra charges, but finds that he cannot do so because the patient has been issued an unlimited instead of a limited policy.

Dr N S Scarcello, Worcester, had offered the following resolution: "That the Blue Shield through its employees determine accurately an applicant's yearly earnings before issuing the policy, and secondly, that these earnings be reviewed each year." This resolution had been adopted by the Committee on Public Relations.

The Executive Committee recommended that the Council refer this matter back to the subcommittee appointed to investigate the relations between members of the Massachusetts Medical Society and the Blue Cross and Blue Shield, for further study and conference with Dr Charles G Hayden, medical director of the Blue Shield and Blue Cross.

In order that the matter might be discussed clearly and authoritatively the President had invited Dr Charles G Hayden and Dr James C McCann, president of Blue Shield, to attend this meeting of the Council. Dr Bagg asked the Council, therefore, to give unanimous consent to Drs Hayden and McCann to speak on the question. This consent was granted.

*Advance necessitated by midyear meeting of House of Delegates of American Medical Association

Dr N S Scarcello, Worcester, spoke against returning the question to the committee, arguing strongly in favor of his original resolution adopted by the Committee on Public Relations that Blue Shield ascertain an applicant's yearly earnings and review them yearly. He then moved the adoption of the resolution. The motion was seconded.

Dr James C McCann, in discussing the resolution, mentioned the original close integration between the Council of the Society and the Blue Shield, which the Council had created — an integration that was apparently now lacking. He spoke at length on the difficulties of determining the income level that should separate limited from unlimited policies, and the difficulties and the cost of frequent appraisal of policyholders' incomes.

Dr Charles G Hayden indicated the economies that Blue Cross and Blue Shield are establishing in cutting their payrolls, thereby effecting savings that can be used for increased benefits to subscribers and to accumulate proper reserves as required by the Commissioner of Insurance.

Dr Elmer S Bagnall, Essex North, called attention to the fact that each district has a professional service committee established under the by-laws of the Blue Shield, and that in the Blue Shield is a central professional service committee. Each district has also a district administrative committee.

Dr James P O'Hare, Suffolk, agreed with Dr Scarcello that the responsibility for determining the income of subscribers is not one that the physicians should assume.

After further discussion by Drs John Fallon, Worcester, J J Curley, Worcester North, Charles G Hayden, James C McCann, C C Lund, Suffolk, and Frank R. Ober, Suffolk, Dr Harold R Kurth, Essex North, offered an amendment to Dr Scarcello's resolution by suggesting that the whole problem of the question of income be referred back to the Subcommittee on Blue Cross and Blue Shield Problems of the Committee on Public Relations for further study after consultation with Dr Charles G Hayden. The motion was seconded by Dr Bagnall, Essex North. Dr Scarcello raised as a point of order the fact that the amendment controverted the resolution.

The point of order being upheld, the original motion was put to vote and failed of passage.

On motion of Dr M Fremont-Smith, Suffolk, seconded by Dr F R Ober, Suffolk, the question was referred back to the committee for further study.

The President then called attention to the fact that establishment of a Woman's Auxiliary was under way, as reported to the Committee on Public Relations by Dr Milton J Quinn, Middlesex East.

On motion of Dr J V McHugh, Worcester North, duly seconded, the report of the Committee on Public Relations was accepted by the Council as one of information only.

Committee on Legislation — Dr George R Dunlop, Worcester, *Chairman*.

This informational report, which is as follows, was presented by Dr Dunlop.

Since the last meeting of the Council the Committee on Legislation met and authorized Dr Elmer S Bagnall to represent the Massachusetts Medical Society during the hearings on the Taft-Smith-Ball-Donnell Bill (S 545) before the Subcommittee of the Senate Committee on Labor and Public Welfare. During the summer Dr Bagnall called the Subcommittee on National Legislation together for a study and discussion of S 545 preceding his testimony before the Senate Committee. The bill was evaluated and measured by the basic principles governing medical-care plans as published by the Massachusetts Medical Society on February 6, 1946. It was recommended that greater emphasis be placed upon public health and community preventive medicine, a larger appropriation be allocated for research, greater powers be given to all advisory councils and partial aid to those who could pay in part for their medical care be eliminated.

On Wednesday June 4, 1947, Dr Bagnall testified before the Subcommittee on Labor and Public Welfare to the effect that the Massachusetts Medical Society favored the ultimate creation of a federal Department of Health at cabinet level, headed by a physician. In the light of the principles adopted by the Society for governing medical-care plans he showed that S 545 had certain strengths and certain weaknesses. Recommendations were made for clarification and strengthening the provisions in this bill. A copy of Dr Bagnall's testimony is available under the reports of the hearings on this legislation.

On June 5, 1947, the Senate Committee on Expenditures in the Executive Departments agreed to report on S. 140, as amended. It was the opinion of the Subcommittee on National Legislation of the Society that "if federal activities in the field of public health are to be elevated to cabinet level, they should not be combined with education, security or any other field." Senator Taft, himself believed that health was too important to be combined with welfare and education.

Congress adjourned without any action on the bill and as the Social Security Board is to be investigated favorably action on the bill in its present form seems unlikely.

House Bill 705 which later became House Bill 1921 was finally rejected by the Massachusetts House of Representatives on June 19, 1947. This bill prohibited the employment in schools of persons suffering from tuberculosis in communicable form and provided for periodic examination of school employees.

House Bill 274 providing for an appointment of a special commission to investigate and study the public-health laws and policies of the Commonwealth was combined with H 1870 and H 2137 to become H 2338. This latter was enacted and signed by the Governor on June 30, 1947.

It might be important to note that during the year 1947-1948, all petitions to come before the General Court must be filed on or before the first Wednesday in December. Petitions after this date will have to come before the Rules Committee.

Dr Dunlop moved the acceptance of the report, the motion was accepted, and it was so ordered by vote of the Council.

Committee on Arrangements — Dr G Guy Bailey, Jr, Middlesex South, *Chairman*.

This informational report, which is as follows, was presented by the President in the absence of Dr Bailey.

The Committee on Arrangements reports that it has selected the dates of May 25, 26 and 27, 1948 for the annual meeting of the Society and has selected the Hotel Statler in Boston as the place of the meeting.

It is the plan of this committee to try to encourage more and better scientific exhibits at next year's meeting, and a section of the foyer has been set aside for this purpose

Dr A A Hornor, Suffolk, moved the acceptance of the report. The motion was seconded, and it was so ordered by vote of the Council

Committee on Finance — Dr Robert W Buck, Suffolk, *Chairman*

This report, which contains two recommendations, was presented by Dr Buck as follows

The Committee on Finance has approved additional expenditures amounting to \$300 to cover the cost of dinner meetings of two committees

The Finance Committee has also voted to approve the suggestions made by the treasurer of the Society, Dr Eliot Hubbard, as found in the report of the Executive Committee of the Council, February 5, 1947. Dr Hubbard suggested that if the annual dues were raised to \$25 00, he would like to make the following recommendations

"1 That the refund to district societies be increased from \$4000 a year to \$8000"

The Committee on Finance approves this suggestion and recommends its adoption

"2 That the total amount of the assets of the General Fund be set at \$250,000, and not be increased each year by reinvestment of surplus, and that in any given year, after running expenses have been paid and aid to the Boston Medical Library and other beneficiaries given, the balance of income over expenditures be automatically turned over to the Building Fund. This fund so augmented would assure the purchase of adequate headquarters at the proper time and would allow for a Building Fund endowment, the income from which would support the running of this establishment"

The Finance Committee approves this suggestion and recommends its adoption

Dr Buck moved the acceptance of the report as a whole. The motion was seconded, and it was so ordered by vote of the Council

Dr Buck then moved the adoption of the first recommendation, which is that the refund to district societies be increased from \$4000 to \$8000 yearly, after the annual dues have been increased. The motion was seconded, and it was so ordered by vote of the Council

Dr Buck moved the adoption of the second recommendation as printed above. The motion was seconded and it was so ordered by vote of the Council

Committee on Cancer — Dr Shields Warren, Suffolk, *Chairman*

This report, which contains one recommendation, was presented by Dr Allen G Rice, Hampden, and is as follows

The Palmer Memorial Unit of the New England Deaconess Hospital has asked approval of the Suffolk District Medical Society for the establishment of a Cancer Detection Clinic. In view of the special character of the problem this request was turned over to the Committee on Cancer by the Suffolk District Medical Society

The Committee recommends that the request of the New England Deaconess Hospital for the establishment of a Cancer Detection Clinic be approved

It is well for members of the Society to be aware of the wide opportunities that exist for funds for cancer research and for cancer education. The United States Public

Health Service has made available to each approved medical school a sum up to \$25,000 for the teaching of cancer. The budget of the United States Public Health Service approved by the last Congress carried a \$14,000,000 item for work in the field of cancer, chiefly along the lines of education and research

The Massachusetts Division, Inc., of the American Cancer Society has raised approximately \$358,000 this year, and the American Cancer Society in its nation-wide campaign has raised \$11,500,000. The grants made in the Commonwealth by the national society have been chiefly on a research-grant basis, and hence, largely restricted to metropolitan areas. The Massachusetts Division, Inc., of the American Cancer Society has a much more intimate knowledge of the situation that exists within the state, and consequently has been able to make a far wider distribution of its funds. Support of research, service or education has been carried out in the following communities: Boston, Brockton, Brookline, Cambridge, Fall River, Lowell, Pittsfield, Springfield, Westfield, Worcester and Wrentham

Dr Rice moved the acceptance of the report as a whole. The motion was seconded by Dr F R Ober, Suffolk. Dr Bagg then asked the consent of the Council to permit Dr Clifford C Franseen to discuss the proposed Cancer Detection Clinic and answer any questions that councilors might have concerning it. This consent was unanimously granted

Dr Franseen explained that according to recommendations of the American Cancer Society and the American College of Surgeons, the approval of the County Medical Society must be obtained before such a clinic is established. In this instance, because of a special situation, the Suffolk District Society had turned the request over to the Committee on Cancer, which presented it to the Council for approval. The special situation was that the Massachusetts Department of Public Health had funds available from a federal grant to subsidize this clinic for cases in which the patient could not pay the full fee

In the discussion that followed it became apparent that the Council was not convinced that the organization of the clinic had yet reached a stage where the Council was ready to give its approval

Dr N S Scarcello, Worcester, moved that the recommendation be tabled until the plans for the clinic had been completely worked up, when it could be reintroduced to the Council. This motion was seconded, and it was so ordered by vote of the Council

Committee on Physical Medicine — Dr Arthur L Watkins, Middlesex South, *Chairman*

This report, which contains three recommendations requested by the Massachusetts Department of Education regarding establishing standards of training and education in the field of physiotherapy, was presented by Dr Watkins and is as follows

This committee, on April 30, 1947, had referred to it by Dr John F Wostrel, supervisor of private trade schools, Department of Education, Commonwealth of Massachusetts, a request for aid in establishing standards of training and education for the teaching staffs of licensed

private trade schools in the field of physiotherapy. These schools are not approved by the American Medical Association and do not operate on the level required by the American Medical Association.

In reply to this request the following recommendations are made:

1 The technical director of a school of physical therapy should be certified by the American Registry of Physical Therapy Technicians and have a minimum of five years' experience as a physical therapist, working in clinics or hospitals employing other registered physical therapists.

2 Assistant directors or instructors should be certified by the American Registry of Physical Therapy Technicians and have two years' experience in a hospital or clinic employing other registered physical therapists.

3 It is further recommended that the minimum requirement for entrance to all licensed trade schools in the field of physical therapy (physiotherapy) include two years of college with courses in the basic sciences or in case high school graduates are admitted, there should be a minimum of two academic years of college level including courses in basic sciences.

Dr Watkins moved that the recommendations as published be adopted. The motion was seconded by Dr Bagnall, and it was so ordered by vote of the Council.

Dr Watkins then moved the acceptance of the report as a whole. The motion was seconded by Dr Bagnall, and it was so ordered by vote of the Council.

Committee to Meet with General Hawley — Dr Humphrey L. McCarthy, Norfolk, *Chairman*

This informational report (Appendix No. 4), containing the agreement entered into between the Massachusetts Medical Society and the Veterans Administration in accordance with the Kansas Plan, was presented by Dr Bagg in the absence of Dr McCarthy.

The acceptance of this report and the approval by the Council of a board of review to be nominated by the President according to Section 9 of the agreement were moved by Dr Hornor. The motion was seconded by Dr Ober, and it was so ordered by vote of the Council.

Committee to Survey Malpractice Insurance in Massachusetts — Dr Carl Bearse, Norfolk, *Chairman*

This report (Appendix No. 5), which contains four recommendations, was presented by the chairman, who moved the adoption of the first recommendation, that the Massachusetts Medical Society should not undertake its own liability insurance at this time.

The motion was seconded by Dr Hornor, and it was adopted by vote of the Council.

Dr Bearse moved the adoption of the second recommendation, that no one insurance company be recommended exclusively at this time. The motion was seconded by Dr Ober, and it was adopted by vote of the Council.

Dr Bearse then moved the adoption of the third recommendation, that a special committee of five fellows be appointed by the President to act in an

advisory capacity to the Society and insurance companies in regard to malpractice insurance. The motion was seconded by Dr Bagnall, and after some discussion it was so ordered by vote of the Council.

Dr Bearse moved the adoption of the fourth recommendation, that the present committee be discharged. This motion was seconded by Dr Hornor and was adopted by vote of the Council. Dr Bearse then moved the acceptance of the report as a whole, the motion was seconded, and it was so ordered, with thanks, by vote of the Council.

Committee on New England Postgraduate Assembly —

Dr Leroy E. Parkins, Suffolk, *Chairman*

This report, of progress only, was presented by the chairman and is as follows:

The Committee invited the other New England state medical societies to participate in organizing an assembly, all accepted and appointed members to a joint executive committee.

A program committee was appointed representing all the societies; the program is being published in the *Journal*, and a copy will be mailed to each registered physician in New England.

The Assembly will be held October 29 to 31, 1947.

Dr Parkins moved its acceptance. This motion was seconded by Dr Hornor, and it was so ordered by vote of the Council.

Committee to Establish a Pension Plan — Dr Robert W. Buck, Middlesex South, *Chairman*

This report (Appendix No. 6) was presented by the chairman.

In offering the report, Dr Buck stated that the committee wished to amend its recommendations so that a pension of 50 per cent of the salary at the time the insurance is written, instead of the average salary, be provided as a goal. If the recipient is granted increase in wages between the time he becomes eligible and the time he reaches the retirement age, proportionate increases in benefits must be added to the terms of the policy, but in no case, irrespective of the age at the time the policy is written, is the final monthly pension payment to be more than \$200.

Dr Buck then moved the adoption of the recommendation as amended, the motion was seconded by Dr Chapin and it was so ordered by vote of the Council.

Dr Buck moved the acceptance of the report as a whole, the motion was seconded and it was so ordered by vote of the Council.

Advisory Committee on School Medical Services — Dr Stewart H. Clifford, Middlesex South, *Chairman*

This report (Appendix No. 7) was offered by the President. After some discussion of the difficulties that the Committee had encountered in its deliberations, Dr Bagnall moved that the recommendation of the Executive Committee that the report

be referred back to the committee for further study be adopted. The motion was seconded and it was so ordered by vote of the Council.

Report of the Massachusetts Representatives to the House of Delegates of the American Medical Association

This report (Appendix No. 8) prepared by Dr. David D. Scannell, Norfolk, was submitted by the President. Its acceptance was moved by Dr. Hornor, the motion was seconded, and it was accepted by vote of the Council.

Committee to Study Special Services — Dr. Leland S. McKittrick, Suffolk, Chairman

The report of this committee (Appendix No. 9) was read by the Secretary. Its acceptance was moved by Dr. Hornor and seconded by Dr. Ober.

Dr. George L. Schadt, Hampden, in discussion, moved that a preamble be attached to the report designating it as an interim report until it could be more fully studied by the societies of radiologists, pathologists and anesthetists, and a final agreement reached.

In the course of the discussion that followed, Dr. Bagg made it clear that the above-named societies, the hospital associations, the Blue Cross and the Blue Shield were represented on the committee, and that the committee was unanimously behind the report.

After further discussion the amendment was put to vote and was not accepted, and the report, being put to vote, was unanimously accepted by the Council, and the committee was discharged.

The Secretary read a communication from Mrs. Robert N. Nye, expressing her appreciation for the flowers that had been sent in the name of the Society to Dr. Nye's funeral services. He went on to tell of the gifts of money that had been received by the Massachusetts Division of the American Cancer Society in memory of Dr. Nye, in lieu of flowers, and of the opportunity that existed of adding to this memorial fund.

NEW APPOINTMENTS

The following new appointments were then offered by the President and were confirmed by vote of the Council.

To the Advisory Committee on Malpractice Insurance

Dr. Carl Bearse, Norfolk, Chairman
Dr. William J. Brickley, Suffolk
Dr. Maurice Fremont-Smith, Suffolk
Dr. Guy L. Richardson, Essex North
Dr. Horatio Rogers, Suffolk

To the Committee of Seven

Dr. Reginald Fitz, Suffolk, Chairman
Dr. Frank B. Carr, Worcester
Dr. W. A. R. Chapin, Hampden
Dr. Lawrence R. Dame, Franklin
Dr. Peirce H. Leavitt, Plymouth
Dr. Dwight O'Hara, Middlesex South
Dr. Walter G. Phippen, Essex South

NEW BUSINESS

The following letter to the President was read by the Secretary.

Dear Dr. Bagg:

There is one matter in connection with my administration as president of the Massachusetts Medical Society that I feel has been left in the category of unfinished business, and I feel that I should call it to your attention specifically on this account.

The matter of establishing the secretaryship of the Society on a full-time basis was discussed frequently at the meetings of the Committee of Seven during 1945 and 1946. It was brought before the Council by Dr. Ober's special committee and accepted in principle at the meeting of February 5, 1947. You will remember that we talked it over before you approached Dr. Tighe on the subject the last time he was at the society headquarters. In spite of all this priming, somehow there did not seem to be a suitable way to bring it before the Council at the annual meeting and so it has gone on.

My feeling that we need a full-time secretary is very strong and my experience during the period of Dr. Tighe's illness and absence confirms this feeling in a most conclusive manner. There are, furthermore, matters which should be kept on record in connection with the annals of the Society which have been and are being forgotten every day. Dr. Burrage's history stopped twenty-five years ago and it seems to me that the activities of the Society during the past quarter-century transcend all previous work and should be recorded before our generation completely passes away. I furthermore believe there is a vital need for more accounts of the work of the thirty-odd committees of the Society to be published in the *New England Journal of Medicine* because it is only by such publication that the fellows as a whole have an opportunity to know what is being done and what is being thought. There are, of course, other reasons with which I know you are familiar.

The real purpose of my writing this letter is to place formally in your hands my belief in the need and my hope that some way may be worked out for the action which will lead to the suitable arrangement for a full-time secretary for the Massachusetts Medical Society.

With all good wishes, I am

DWIGHT O'HARA, M.D.

Dr. O'Hara, after a few explanatory remarks, moved that the President be asked to nominate a Committee of Seven to consider the matter of a full-time secretaryship, with power to act, to report to the Council at its next meeting. Dr. Fremont-Smith seconded the motion. Dr. Hornor offered as an amendment, which was accepted by Dr. O'Hara, that the committee also have the power to determine the salary it might offer.

Dr. Bagg suggested that the committee should also define the fields of Secretary and Executive Secretary and Director of Information so that there will be no overlapping of functions.

The question was put to vote and the motion was accepted by the Council.

The following letter to the President was then read by the Secretary.

Frequent calls for the recommendation of names of physicians for the treatment of patients throughout the state continue to come into the main office of the Society.

In our experience the present method of referring such inquiries to the secretary of the proper district society is cumbersome and too dilatory.

Hence, I would like to suggest that the matter be opened and referred once more to the appropriate committee for further study in order to provide better service to the public.

JOSEPH GARLAND, M.D., Secretary

As recommended by the Executive Committee, this matter was referred to the Committee on Public Relations by vote of the Council.

The following communication from the trustees of the Boston Medical Library was read by the Secretary for purposes of information.

Dear Dr. Garland

As secretary of the Boston Medical Library I acknowledge with great pleasure your letter dated June 1, 1947, informing me of the action taken by the Council of the Massachusetts Medical Society with respect to the Boston Medical Library.

In accordance with this action, the Trustees of the Boston Medical Library have voted to propose changes in their by-laws to be acted upon at a special meeting of the Corporation on November 17, 1947, whereby a new class of membership in the Boston Medical Library will be known as Massachusetts Medical Society Member will be created. Any non-resident fellow of the Massachusetts Medical Society, active or retired as long as he remains in good standing after January 1, 1948, will automatically be in this class. He will be given the same privileges as other members, including of course, the taking out of books and periodicals. Another change in the by-laws which has been proposed will be the addition of four trustees to be appointed by the Massachusetts Medical Society. A copy of these revised by-laws will be sent to you after their adoption by the Corporation.

It is hoped that in this way a closer co-operation of the activities of the Massachusetts Medical Society and the Boston Medical Library will be effected.

BENJAMIN CASTLEMAN M.D. Secretary

Dr. L. E. Parkins, Suffolk, offered the resolution that the Committee on Postgraduate Assembly be directed to enter into discussions with the Assembly representatives of the other New England states, as well as with the Council of New England state medical societies, for the purpose of setting up an organization to carry on the future work of the Assembly, and that after such an organization had been agreed upon by the committee it be reported to the Council for final approval.

The resolution was seconded and was accepted by vote of the Council.

The following communication was read by the Secretary, who moved its referral to the proper committee.

The accompanying letter concerns a special project for the medical care of children of veterans at Harvard University. This matter was presented to me during the summer as one approved by the State Department of Public Health and a plan about to be placed in operation with the opening of the school year.

The sponsors have shown every effort to obtain the approval of the Massachusetts Medical Society in advance of the plan's operation. This has not been possible under our By-Laws.

I offer this matter as an item of new business for referral for study by the appropriate committee. I will be at the service of the committee for whatever additional information it may require.

JOHN F. CONNOR M.D.

Director of Medical Information and Education

Dear Dr. Conlin

This letter is to confirm our telephone conversation relative to obtaining official approval by the Massachusetts Medical Society of a special project for the care of children of veterans at Harvard University.

During the past winter several medical problems arose among the children of veterans at Harvard that gave

cause for concern by those in medically responsible positions at Harvard and at Harvard Deacons Village.

The veteran students in general were on small government stipends not allowing for adequate medical care for their children. Arlic V. Bock, M.D. requested Allan M. Butler M.D. to see if he could devise some means whereby such care could be provided. Dr. Butler consulted Gerald N. Hoefel M.D., Dorothea M. Moore M.D., and Ralph A. Ross M.D. pediatricians of Cambridge who were caring for many of the children in this area and Al Weller M.D. of Arlington who was caring for a group at Harvard Deacons. These physicians confirmed the need of some type of medical aid and indicated that they were carrying a heavy case load without adequate compensation for services rendered. Inquiries indicated that Government funds could be made available from the Children's Bureau via the Massachusetts Department of Public Health via the State Division of Maternal and Child Welfare, provided it be done as a study as well as a service project.

The request for such funds was submitted as follows.

The purpose of this project is to give medical care for children of G. I.'s who are so small Government stipends at Harvard and at Fort Devens. These students come from many states other than Massachusetts. There will be no economic or racial determination of eligibility and no other limiting factor. It will be sponsored by Massachusetts General Hospital. The Child Health service will notify the G. I. students concerning the availability of the service and will give them exact information as to how to secure this service.

The service to these children will be given through child health conferences, pediatric and consultation service in the home, out patient care at the Massachusetts General Hospital and hospital medical and surgical care at the Massachusetts General and other qualified hospitals. The special diagnostic and treatment services at the Massachusetts General will be available to this child health service. The Massachusetts General Hospital provides unusually good facilities staffed by personnel with the highest professional qualifications and used as a teaching hospital by the Harvard School of Public Health. It is licensed by the Massachusetts Department of Public Health. Harvard University will furnish office space at Harvard and conference space and facilities both in Cambridge and at Fort Devens.

Consultation service in the homes will be given through practicing pediatricians who are licensees of the American Board of Pediatrics. The cost will be \$10.00 per home visit.

All physicians will be licensed to practice in Massachusetts. There will be also a part time medical director.

He will be a senior pediatrician who is a licensee of the American Board of Pediatrics, a member of the Staff of the Children's Medical Service, Massachusetts General Hospital and a member of the Department of Pediatrics of Harvard or Tufts University.

The two full time pediatricians will be graduates of a Grade A medical school and will have had an internship and one or more residencies which meet the qualifications of the American Board of Pediatrics.

Consultants will be physicians who are licensees of the American Board covering their particular field of specialty.

The public health nurses meeting the qualifications of the supervisory nurse of the Massachusetts Department of Public Health will be employed under the supervision of the Bureau of Public Health Nursing of the Massachusetts Department of Public Health. They will do generalized service for the entire family.

Nutrition and medical social consultation will be available through the Massachusetts Department of Public Health.

Consultation service will also be available through the Division of Maternal and Child Health.

Two full time clerks will be employed.

There are at present, at Harvard, 1412 children of G I's. This total number will increase during the year due to approximately 350 pregnancies. Therefore, we base our request for funds on 1500 children at a cost of \$35.00 per child.

The operation of this service provides an excellent opportunity for statistical analysis of this type of care and for study of administrative problems. For this purpose, a principal statistical clerk, a statistical machine operator and rental of statistical machine, equipment and supplies are essential. The Harvard School of Public Health will participate in the statistical analysis of this type of care and in study of administrative problems. The cost of such analysis is budgeted separately from the cost of providing the actual health and medical care.

Quarterly reports of services rendered will be made to the Division of Maternal and Child Health covering the number of children receiving each type of service including attendance at well child conferences, home visits, consultant visits in the home, number of outpatient visits and number of hospital days' care per child, with diagnosis and types of treatment. These forms will be submitted when available.

There is every reason to believe that there will be the same need of child health services next year. A request to continue this service should, therefore, be anticipated.

The funds were made available to the State of Massachusetts to be administered by the Massachusetts General Hospital. Harvard University has agreed to supply office and clinic space and will furnish both with such furniture as is appropriate for the needs of the project.

At conferences held with representatives of the Children's Bureau of the State Division of Maternal and Child Health and with representatives of Cambridge public-health services it has been emphasized that official approval of the medical profession be obtained before proceeding further.

FRANCIS C. McDONALD, M.D.

The motion was seconded and carried, and the communication was referred by the President to the Committee on Medical Education.

The following communication was read by the Secretary, who moved its referral to the proper committee.

Dear Dr. Garland:

I am writing to bring the following matter to the attention of the Officers and Council of the Massachusetts Medical Society:

The Committee on Fetus and Newborn of the American Academy of Pediatrics is working out a program to improve the facilities for the care of newborn infants which will include medical, nursing and hospital care, medical social services and the need for training of personnel.

In an effort to activate this program at the State and eventually at the local level, Dr. Stewart H. Clifford, the Chairman of the Committee, with the approval of the Executive Board of the Academy, has requested the State Chairmen to appoint a State committee on Fetus and Newborn. Dr. Clement A. Smith has agreed to act as chairman of such a committee in Massachusetts. Eleven other physicians interested in this problem have been invited to serve on the committee.

The program developed by the National Committee will be presented in detail at the annual meeting of the American Academy of Pediatrics on December 8, 1947, in Dallas, Texas. It is hoped that the Massachusetts committee will begin to function after that time and that eventually there will be local committees to carry out the details of the program in the state.

It is the intention of the American Academy of Pediatrics that this program be carried out with the approval and co-operation of the State Medical Societies.

JAMES MARVIN BATY, M.D.
State Chairman for Massachusetts,
American Academy of Pediatrics

This motion was seconded and carried, and the communication was referred by the President to the Committee on Medical Education.

Dr. B. C. Wheeler, Worcester, then proffered the following invitation from the Worcester District Medical Society:

Mr. President, on behalf of the Worcester District Medical Society, I should like to present a cordial invitation to hold the 1949 annual meeting of this Society in Worcester. It will then have been eleven years since the last annual meeting in Worcester and the Worcester District Medical Society would consider it an honor and a privilege to act as host again. This is pursuant to a unanimous vote of the regular monthly meeting of our District Society held on September 10, 1947.

Dr. O'Hara moved that the invitation be accepted with gratitude and referred to the Committee on Arrangements. This motion was seconded by Dr. Hornor, and it was so ordered by vote of the Council.

There being no further business before the Council, the President announced it adjourned at 1:50 p.m.

JOSEPH GARLAND, Secretary

APPENDIX NO. 2

REPORT OF THE EXECUTIVE COMMITTEE

The Executive Committee of the Council met on September 3, 1947 in Sprague Hall, 8 Fenway Boston, Massachusetts at 4:00 p. m. Dr. Edward P. Bagg, president of the Society, presided. Present were Dr. Daniel B. Reardon, president elect, Dr. Charles J. Kiekham, vice president, Dr. Elliot Hubbard, treasurer and representatives from all the district societies except Barnstable, Berkshire, Hampshire and Worcester.

The record of the meeting of April 23, as presented at the annual meeting of the Council on May 19, 1947 was submitted by the Secretary, and was approved.

COMMITTEE REPORTS

Committee on Membership

The report of the meeting of August 13, 1947, as circulated in mimeographed form, was considered by sections and approved with one correction.

Committee to Study Special Services

President Bagg, in commenting on the appointment of this committee, pointed out that the members representing the various associations were all approved by those associations so that whatever decisions were arrived at might be considered as authoritative.

The report, which had been distributed in mimeographed form with the Circular of Advance Information, was read by the Secretary and its acceptance is recommended by the Executive Committee.

Considerable discussion took place on the statement by Dr. Kemp Franklin on the failure of Blue Shield to determine accurately an applicant's yearly income, and the resolution offered by Dr. Scarcello, Worcester, that the Blue Shield through its employees determine accurately an applicant's yearly earnings before issuing the policy and secondly, that these earnings be reviewed each year.

The difficulties and the cost of determining these facts were brought out, and it was stated that the physician interviewing a patient can easily ascertain his income and so report to the Blue Shield.

The Executive Committee recommends that the Council refer this matter back to the subcommittee appointed to investigate the relations between members of the Massachusetts Medical Society and the Blue Cross and Blue Shield, for further study and conference with Dr. Charles G. Hayden, medical director of the Blue Shield.

That section of the report of the Committee on Public Relations containing the report of the Subcommittee on the Formation of a Woman's Auxiliary was discussed, and Dr. John F. Conlin, Suffolk, director of medical information and education, reported the establishment of the State Advisory Council and progress in Suffolk and Norfolk, two of the five districts that have approved district auxiliaries.

The acceptance of the report as a whole is recommended by the Executive Committee.

Committee on Legislation

The Executive Committee recommends the acceptance of this report.

Committee on Arrangements

The Committee on Arrangements reports that the next annual meeting of the Society will take place May 25 to 27, inclusive, at the Hotel Statler in Boston.

The Executive Committee recommends the acceptance of this informational report.

Committee on Finance

The committee approved the recommendations made by the Treasurer, at the Council meeting on February 5, 1947, provisional on the raising of the annual assessment to \$25 00, that,

- 1 The refund to district societies be increased from \$4000 a year to \$8000
- 2 The total amount of the assets of the General Fund be set at \$250,000 and the balance of income over expenditures be automatically turned over to the Building Fund

The Executive Committee approves this report and recommends its adoption by the Council

Committee on Cancer

The Committee on Cancer, in recommending approval of the request of the New England Deaconess Hospital for the establishment of a cancer-detection clinic, points out the opportunities that exist for funds for cancer research and cancer education, as shown in the committee's report.

The Executive Committee recommends that the question be referred to the Council without prejudice and that Dr Shields Warren, chairman of the committee, be asked to present the report and discuss it

Committee on Physical Medicine

The Executive Committee recommends the acceptance of this report and the adoption of its recommendation

Committee to Meet with General Hawley

This report contains the agreement, according to the Kansas Plan, entered into by the Massachusetts Medical Society and the Veterans Administration and signed by the President and Secretary in accordance with the vote of the Council on May 19, 1947

The Executive Committee recommends the acceptance of this report and the approval by the Council of a board of review to be nominated by the President according to Section 9 of the agreement.

The President at this point read a communication from the Council on Medical Service of the American Medical Association asking that representatives be sent to a conference on "Veterans Administration Home Town Medical Care Program" to be held at the Headquarters of the American Medical Association in Chicago on November 6, 1947

The Executive Committee recommends that the President be authorized to nominate such representatives

Committee to Study Malpractice Insurance in Massachusetts

President Bagg, in presenting this report to the Executive Committee, called particular attention to its excellence and to the tremendous amount of work that had gone into its compilation

The Executive Committee recommends the acceptance of this report and the adoption of its first three recommendations. It further recommends that the fourth recommendation, asking for the discharge of the committee, be not adopted, but that the present committee, with proper replacements, be continued

Committee on New England Postgraduate Assembly

The Executive Committee recommends the acceptance of this informational report

Committee to Establish a Pension Plan

Dr Eliot Hubbard, in discussing this excellent report, pointed out that there is only one employee of the Society of long enough standing to be considered as a candidate for a policy under such a plan. Since the average salary of this employee over the years he has been with the Society has

been much less than his present salary, it seems fairer that a policy taken out for him should be based on his salary at the time the policy is dated

The Executive Committee recommends that this matter be referred back to the committee for further study

Advisory Committee on School Medical Services

This report was the subject of considerable discussion in the Executive Committee, particularly regarding the recommendation that the present law requiring annual examination of school children be amended to provide for less frequent but more adequate examination. Discussion of this recommendation brought out the observation that no member of the committee had anything to do with school services and that it might be preferable to augment the committee or refer the matter to a group of school physicians for further consideration. Further discussion hinged about the controversial point as to whether school health should be under the department of education or that of health. This was not settled.

Debate over the desirability of the Society's drawing up a bill and arranging its introduction to the legislature was lengthy and varied. The Executive Committee finally agreed to recommend that it would be better for the Society to approve a bill introduced by some other agency, than to initiate one itself.

The Executive Committee hesitates to give an opinion on the thirteen recommendations of the Committee on Public Health that were referred to the Committee on School Medical Services. It does recommend the adoption by the Council of Recommendation 2, asking that a representative be sent to a conference on school health sponsored by the American Medical Association.

The remainder of the report is recommended for acceptance as one of progress, to be referred back to the committee for further study.

The Executive Committee recommends the acceptance of the excellent report of the Massachusetts representatives to the meeting of the House of Delegates of the American Medical Association at Atlantic City on June 9, 10, 11, 12, 1947

OTHER BUSINESS

A letter was read from the Secretary requesting consideration of the matter of patients who wish to have physicians referred to them by the Secretary's office. The Executive Committee recommends that this problem be referred to the Committee on Public Relations.

A letter from Dr O'Hara was read stressing the urgency of making the Secretaryship a full-time position. The Executive Committee recommends that this matter and the relations between the Secretary, the Director of Medical Information and the Executive Secretary be referred to a committee of seven, to report at an early meeting of the Council for action.

A communication was read from Mr James A Morrison, manager of the Convention Bureau of the Boston Chamber of Commerce, addressed to Mr Boyd, the executive secretary.

This letter called attention to the new policy of the American Medical Association House of Delegates of having mid-year meetings away from Chicago. It was suggested that if the Massachusetts Medical Society cared to extend an invitation to the House of Delegates to hold its mid-year meeting and convention in Boston in the not too distant future, the Boston Chamber of Commerce would be glad to co-operate.

This matter was referred to the Secretary, to ascertain the opinions of the Massachusetts delegates and to act accordingly.

Dr John F Conlin, director of medical information and education, introduced the subject of the activities of the National Physicians Committee and the attitude that the Society should take toward them.

Dr Conlin gave the information that the National Physicians Committee is the third most powerful lobby in Washington, having expended about \$600,000 in the last year, mostly for lobbying. Although its objectives are approved by the House of Delegates of the American Medical Association, its methods have aroused considerable criticism. Na-

sons legislators and others are justly confused as to who represents the medical profession of the country.

The Executive Committee makes no recommendation for action by the Council.

A letter was read from Dr. George F. H. Bowers and other relatives of the late Dr. Walter P. Bowers expressing appreciation for the floral tribute sent to the funeral services.

The Secretary asked for instruction concerning the use of the Society's addressograph by district societies and others and was given authority to handle this matter with Mr. Boyd, as office business.

The meeting was adjourned at 6.30 p.m.

JOSEPH GARLAND, Secretary

APPENDIX NO. 3

REPORT OF COMMITTEE ON PUBLIC RELATIONS

At the last meeting of the Public Relations Committee, June 25, 1947, President Bagg expressed for the members of the Committee their sincere appreciation of the excellent work that Dr. Albert A. Hornor had performed as Secretary of the Committee on Public Relations. Dr. Harold R. Kurth, Essex North, was then elected as the new Secretary for this Committee.

President Bagg further reported that he had appointed as representatives to serve with Dr. Norman Welch on the Council of the New England state medical societies, Dr. Archibald J. Douglas, Hampden and Dr. Gerald N. Hoeflich, Middlesex South.

Dr. Charles D. McCann, Plymouth, reported for the subcommittee that was appointed at the last meeting to investigate the relation between members of the Massachusetts Medical Society to the Blue Cross and Blue Shield as follows:

At the March meeting of the Public Relations Committee Dr. Harold R. Kurth, Essex North, offered a resolution in regard to the arrangement in the Blue Cross setup wherein the anesthetists are reimbursed only when they are on salary in a hospital.

The question then came up about professional and hospital service in general. After a good deal of discussion the undersigned committee was appointed by Dr. Dwight O'Hara to study any problem that might exist between members of the Massachusetts Medical Society and the Blue Cross and Blue Shield.

In order to obtain information in this respect the committee sent out a letter to the members of the Committee on Public Relations asking them to gather information concerning this problem and to bring that information to the next meeting of the committee.

On May 13, 1947, this subcommittee met at the Harvard Club with representatives of the Anesthesiological Society, the Roentgenological Society and the Pathological Society. Drs. Everson and Wiggin, Drs. Sosman, Altman and Mueller, and Drs. Castleman and Nickerson represented the above-named societies.

These representatives were in accord that the setup in regard to professional and hospital service was very much mixed up, and it was their belief that services rendered by those groups should be taken care of under the Blue Shield program rather than by the Blue Cross.

At the annual Council meeting of the Massachusetts Medical Society Dr. Sosman offered a resolution to this effect, and it was voted by the Council that the President appoint a general committee from the Society to study the whole Blue Cross and Blue Shield plan.

In view of this decision this committee hopes that this report will be accepted and the committee discharged.

ALBERT A. HONOR, M.D.
HAROLD R. KURTH, M.D.
CHARLES D. MCCANN, M.D.

As a result of the request by the subcommittee that the members of the Committee on Public Relations gather what information they could concerning this problem to be presented at this meeting of the committee, there ensued considerable discussion with reference to the relation of the members of the Blue Cross and Blue Shield.

Dr. Henry A. Robinson, Norfolk South, brought forth the criticism that in the lists of participating physicians of

the Blue Shield there was no way of distinguishing between regular physicians and osteopathic physicians. It was felt that this might lead to unnecessary confusion unless proper distinction be made. No action was taken by the Committee on Public Relations with reference to this criticism.

Dr. B. Appel, Essex South, stated that his district had requested him to present a resolution which was unanimously accepted by Essex South that medical service should not be considered under Blue Cross. He stated that the staff of the Lynn Hospital had also recorded itself as unanimously opposed to medical service being considered under Blue Cross. No action was taken by the Committee on Public Relations with reference to this resolution as it was felt that this matter at the present time was being discussed by the new Committee on Special Services.

Dr. H. M. Kemp, Franklin, stated that very little attempt was being made by Blue Shield to determine accurately an applicant's yearly income. This is necessary in determining whether an applicant is entitled to a limited or unlimited type of policy. At the present time the applicant's statement of income is accepted as correct. Attention was called to the fact that often a physician was entitled to make extra charges, fully aware that his patients' income was above the accepted \$3000 but found that he could not do so because the patient had been issued an unlimited policy, whereas in reality he should have been issued a limited policy thereby allowing the attending physician to make an extra charge. Such a situation often leads to some confusion in the patient physician relation.

Dr. N. S. Scarcello, Worcester, offered the following resolution: That the Blue Shield through its employees determine accurately an applicant's yearly earnings before issuing the policy, and secondly, that these earnings be reviewed each year.

This resolution was adopted by the Committee on Public Relations.

There also followed some general discussion, more or less informative in nature, namely that Blue Shield allowed a larger fee schedule for obstetric care to the specialist than to the general practitioner doing the same type of work. It was the opinion of the Committee on Public Relations as a whole that at some future time there might be some more favorable revision of the fee schedule of the Blue Shield.

Following this presentation by the various members of the Committee on Public Relations, Dr. McCann moved for the acceptance of the report of this special subcommittee for the Blue Cross and Blue Shield problem. The report was accepted but the recommendation that this committee be discharged was rejected. It was believed that this subcommittee should continue to function to consider such additional information as may in the future be brought to its attention with reference to Blue Shield and Blue Cross problems and to report its findings to the Committee on Public Relations.

Dr. Milton Quinn, Middlesex East, reported for the Committee on the Formation of a Women's Auxiliary, stating that the Council had endorsed such a program for establishing such auxiliaries in the districts that so desired it. The Committee on Public Relations felt that the organization of these auxiliaries should be turned over to Dr. John F. Conlin, director of medical information and education.

Dr. Harold R. Kurth, Essex North, reported for the Committee appointed by Dr. Dwight O'Hara to draw up resolutions expressing the sympathy of the Committee on Public Relations to the family of the late committee member, Dr. Daniel J. Ellison of Middlesex North. A letter to this effect was sent to his daughter, Mrs. Malcolm Stevens, Lowell, Massachusetts.

Dr. John F. Conlin stated that he would assume his new office as director of medical information and education on July 1, 1947. He urged the various members present to call upon him for whatever service he might give them in matters of public relations.

HAROLD R. KURTH, Secretary

APPENDIX NO. 4

REPORT OF THE COMMITTEE TO MEET WITH GENERAL HAWLEY

The committee, since reporting to the Council on May 19, has been successful in securing a contract with the Veterans

Administration providing for examination, treatment and counseling of eligible veterans in Massachusetts. The contract, which follows, was signed for the Massachusetts Medical Society by the President and Secretary on July 23, 1947, was received and approved by the Chief Medical Director of the Veterans Administration, General Paul R. Hawley, on the following day, and has been forwarded to the Director of Supply for appropriate action.

July 1, 1947

To the Administrator of Veterans Affairs

The Massachusetts Medical Society and the Veterans Administration for the purpose of establishing and maintaining a close working relation in order to establish a well-integrated service for providing medical care and treatment for veterans of the State of Massachusetts beyond those services available to the Veterans Administration in existing Veterans Administration facilities and installations, do hereby mutually agree as follows:

- (1) The Massachusetts Medical Society will request all its members to participate in a State-wide program whereby physicians in private practice in the State of Massachusetts will render medical services (examinations, treatments and counsel) in such cases as may be specifically authorized by the Veterans Administration.
- (2) The Massachusetts Medical Society will submit to the Veterans Administration a list of its members who desire to provide service for eligible veterans in the home communities of such veterans. This list may be augmented from time to time as additional physicians may indicate a desire to participate in the program. The physicians so listed will be fee basis physicians of the Veterans Administration. By notice in writing a physician may at any time request that his name be removed from the list of fee basis physicians.
- (3) The Massachusetts Medical Society will assist the Veterans Administration in establishing, for examinations and treatment, a list of competent specialists who meet the qualifications of specialists of the Veterans Administration.
- (4) Lists of physicians submitted by the Massachusetts Medical Society will be broken down by counties or districts in order that the veterans for whom services are authorized may select a physician practicing in his home community. The choice of the physician by the veteran, provided for herein, is not applicable to examinations for pension or compensation rating purposes. Such examinations may be performed only by a physician specifically designated for that purpose by the Veterans Administration.
- (5) Fees for medical services in authorized cases shall be paid by the Veterans Administration to the physician rendering the service in accordance with the Fee Schedule hereto attached, which is made a part of this agreement. The Massachusetts Medical Society warrants that the rates set forth herein are not in excess of the rate of fees charged other persons who are not Veterans Administration beneficiaries for the same or comparable services. It is mutually understood that the fees stated in the Fee Schedule represent the maximum amount that may be charged, and do not represent the amount to be paid in every case. The Veterans Administration will advise each physician of this provision, and will require each physician to certify in submitting his statement of account that the fees charged are not in excess of the fees charged by him for comparable service rendered non-veterans. It is understood that unusually involved cases and services not scheduled will be subject to review and recommendation by the Massachusetts Medical Society to the Veterans Administration for determination of the appropriate fee.
- (6) The Veterans Administration will handle administrative and clerical details in connection with the authorization of examinations or treatments and the maintenance of records, and will arrange for transportation of the veteran if necessary.

- (7) When authorizing treatment, the Veterans Administration will furnish to the veteran, proof of such authorization and a list of fee basis physicians in the county or district in which the veteran is located, in order that he may select his own physician for the services authorized.
- (8) The Veterans Administration will review reports of examinations and services to determine their adequacy. No fees will be paid by the Veterans Administration for reports that are not acceptable to the Veterans Administration or for services rendered in unauthorized cases.
- (9) The Massachusetts Medical Society will establish one or more boards of review composed of physicians. It shall be the duty of such board to review reports, which are deemed by the Veterans Administration to be inadequate or which do not meet the requirements of the Veterans Administration, to recommend, at its discretion, the disqualification of any physician for further work with the Veterans Administration whose work is found by the board to be incomplete or unsatisfactory, to advise and assist the Veterans Administration on other matters within the scope of this program.
- (10) It is agreed that services furnished under the agreement will be performed by licensed physicians. It is further agreed that physicians rendering services hereunder will be citizens of the United States who are doctors of medicine duly licensed to practice medicine and surgery in the State of Massachusetts.
- (11) This agreement shall be effective from July 1, 1947, to July 1, 1948, and may be terminated by either party by giving thirty (30) days' written notice to that effect.
- (12) This agreement, if mutually satisfactory, may be renewed indefinitely for a period of one (1) year each, upon notice in writing to the Veterans Administration at least sixty (60) days prior to the expiration of each period of one (1) year, and written statement from the Massachusetts Medical Society within thirty (30) days after such notification agreeing to the renewal.
- (13) No Member of or Delegate to Congress, or Resident Commissioner, shall be admitted to any share or part of this agreement or to any benefit that may arise therefrom unless it be made with a corporation for its general benefit.
- (14) The Massachusetts Medical Society agrees that in performing this agreement it will not discriminate against any employee or applicant for employment because of race, creed, color or national origin.
- (15) The Massachusetts Medical Society does not propose to make any charge for any service rendered to the Veterans Administration under this agreement.

For your further information, you are advised that it has been found necessary to adopt a policy that no physician will be permitted to accept fee-basis cases for the Veterans Administration in excess of \$6000 in any one year without the prior approval of this office. All Branch Medical Directors have been instructed to enforce this policy and to advise all participating physicians that it is in effect.

It will be further noted that in the paragraph which provides that physicians will be licensed, a provision has been added that they must be citizens of the United States. This is required by law. As you will see, no reference has been made in the proposed Agreement to the item "Notice to Bidders," as this provision does not apply to an Agreement of this type.

It is also understood from the Chief, Out-Patient Division of the Boston Branch Office that Massachusetts Medical Society has agreed to accept the new Veterans Administration Fee Schedule (Form 10-2535a), which is attached hereto and made a part of this Agreement.

MASSACHUSETTS MEDICAL SOCIETY
By EDWARD P. BAGG, President
JOSEPH GARLAND, Secretary

The new Fee Schedule (Form 10-2535a) will be sent by the Veterans Administration to all participating physicians.

The Committee recommends that under Section (9) a Board of Physicians be appointed by the President or Council to review questionable reports or inadequate treatment.

ALLEN S. JOHNSON
JAMES K. BRAGGER
HUMPHREY L. MCCARTHY *Chairman*

APPENDIX NO 5

REPORT OF COMMITTEE TO SURVEY MALPRACTICE INSURANCE IN MASSACHUSETTS

In our report to the Council on February 5, 1947 it was stated that letters had been sent to

- i All fellows of the Massachusetts Medical Society together with a questionnaire.
- ii Secretaries of all State Medical Societies in the United States.
- iii Insurance companies underwriting most of the medical malpractice insurance in Massachusetts

I

SUMMARY OF REPLIES TO QUESTIONNAIRE

Questionnaires mailed	5,530
Questionnaires returned	3,701 (67%)
Resident fellows	3,446 (93%)
Nonresident fellows	255 (7%)

A. Fellows with malpractice insurance

Resident fellows	2,717 (74%)
Nonresident fellows	145 (3%)
	2,862 (77%)

Premiums paid		<i>Average</i>
By 2,717 insured resident fellows	\$85,917 04	\$31 62
By 145 insured nonresident fellows	4,648 02	32 00
	\$90,565 06	\$31 64

Fellows paying less than \$50 00	90%
Fellows paying more than \$50 00	10%
Estimated total amount paid for premiums by total membership of 6,283 (as of January, 1947)	\$153,074 32
(77% of 6,283 (4,838) × \$31 64 = \$153,074 32)	
Estimated total amount paid for premiums by the 5,694 resident fellows (as of January, 1947)	\$145,831 44
(81% of 5,694 (4,612) × \$31 62 = \$145,831 44)	

B. Fellows without malpractice insurance

Resident fellows (including 87 retired)	729 (19%)
Nonresident fellows	110 (4%)
	839

Estimated number of resident fellows without malpractice insurance (19% of 5,694 = 1,082)	1,082
---	-------

Comment Dr A. W. Allen chairman of the Committee on Medical Defense wrote "The annual cost of legal defense for the members not carrying insurance over a period of ten years would not be over \$1,000" and the attorney for the Massachusetts Medical Society wrote that during the ten years prior to January 1, 1947, the Committee on Medical Defense handled

Total number of cases	38
Cases actually tried	7
Judgment for defendant	7
Judgment for plaintiff	None
Cases settled	4
Cases disposed of without trial either by discontinuance or dismissal because of plaintiff's failure to prosecute	19
Cases pending	8

C. Type of practice of insured fellows

Medical	1,547 (42%)
Surgical	1,256 (34%)
X ray exclusively	59 (1%)
X ray plus other type practice	217

D. Companies doing most of the malpractice underwriting in Massachusetts

United States Fidelity and Guaranty Company	1,298 (35%)
Medical Protective Company	1,034 (28%)
Lumbermen's Mutual Casualty Company (including American Motorists)	170 (5%)
Hartford Accident and Indemnity Company	99 (3%)
There are approximately eighteen other companies each insuring less than 1%.	

Comment Council on Medical Service, A. M. A., reported (J. A. M. A. May 10 1947) that of 62 direct inquiries only 21 companies indicated they were writing malpractice coverage. 33 replied negatively, one stated that plans were underway and no replies were received from the other seven.

E. Suggestions volunteered

The Massachusetts Medical Society should have its own indemnity insurance 513 (14%)

The Massachusetts Medical Society should not have its own indemnity insurance 33 (9%)

Illustrative remarks in favor of Society having own insurance

- (1) "I would very much like not to buy commercial insurance if I were assured that I could be fully protected by the Massachusetts Medical Society."
- (2) "I have the impression our membership would be in a stronger position in case of individual suit if it was protected as a group — en masse — and by the Society rather than by many different companies all with different charges and varying degrees of responsibility."
- (3) "I believe the proposal of self insurance by the Massachusetts Medical Society is an excellent one."
- (4) "I am heartily in favor of a mutual co-operative malpractice insurance to be maintained and administered by the Massachusetts Medical Society. But — why not include health, accident, and retirement annuity?"
- (5) "I think the Society could handle this subject far better than the insurance companies."

Illustrative remarks against Society having own insurance

- (1) "I see no reason for a questionnaire of this sort, as I think the Society should stick to medicine and not to insurance."
- (2) "I do not believe we should in any way be in the insurance business. I know of a physician who cannot afford malpractice insurance. How long have we got to carry sunny, selfish, lazy, bottle fed members on our sturdy shoulders?"
- (3) "If any physician fails to carry malpractice insurance, then the Society should not defend him in case of a suit."
- (4) "State medical society insurance is poor business and probably not allowed by our charter. The defendant doctor is exposed to the personality and criticism of his colleagues, some of whom the defendant may not approve. Further the public may think the Society approved the defendant regard less of the action brought against him."
- (5) "Let's stick to our business and let the insurance companies stick to insurance."

Other remarks

- (1) "Returned to practice after three and a half years of service in the Army and have been unable to get coverage. I am a Middlesex graduate and I had coverage in the past but because I did not continue during my services in the Army I am not able to get coverage. I never had a claim against me in over twenty years of practice."

(2) "Was under the impression that the Society recommended and endorsed that all members be insured with United States Fidelity and Guaranty Company"

Comment This impression is probably due to the fact that the policy states, "Special Physicians' Liability Policy for members of the Massachusetts Medical Society"

Comments Of the 27 states furnishing rates

- a The highest rate is paid by California physicians who are individually insured, for \$5,000/\$15,000 coverage they pay \$60 00 annually
- b The lowest rate is enjoyed by Connecticut physicians who have a group policy, for \$10,000/\$25,000 coverage they pay \$12 50
- c In the seven states with group insurance, \$5,000/\$15,000 coverage, physicians pay from \$15 00 to \$30 00

d In the seven states with individual policies, \$5,000/\$15,000 coverage, physicians pay from \$22 00 to \$60 00

e In one state physicians with individual policies pay less than physicians in another state covered by group insurance In New Jersey physicians have individual policies and for \$10,000/\$30,000 coverage pay \$24 00 In Oklahoma under a group policy for the same coverage physicians pay \$26 00 but before the adoption of the group policy, individual physicians paid \$70 00

f In New Hampshire following the adoption of group policy about seven years ago there have been at least four successive reductions in rates For a surgeon with \$5,000/\$15,000 coverage the rate has been reduced from \$50 00 to \$35 00 The medical society also established a medical defense committee with which the insurance company co-operates and which serves in an advisory capacity to the physician against whom a claim has been made and to the insurance company Both the insurance company and the medical society believe that the establishment of the committee has been very helpful in decreasing the number of claims and the cost of premiums

E Liability insurance company organized by physicians
In only one state have physicians organized their own mutual liability insurance company In 1944, physicians in the State of Washington organized the Washington Physician's Service Corporation This company is licensed to underwrite malpractice liability insurance if and when it is deemed necessary or desirable Its capital stock is \$150,000 00 and reserves are \$100,000 00 It is owned by the physicians of that State but is not, as yet, functioning The state medical society still has a group policy

Comment The Council of the Massachusetts Medical Society in 1921 discussed the advisability of developing a mutual insurance company for physicians in Massachusetts A plan was outlined whereby the members could form a company, pay in assessments, have the money deposited in a bank or invested in any way which an executive committee might see fit, and in that way provide for the administration of this type of business When the question was raised as to whether the state medical society could legally engage in this kind of business, Mr E P Saltonstall, at that time attorney for the Massachusetts Medical Society, stated

"Your articles of incorporation contain nothing which would seem to warrant your undertaking to pay verdicts or settlements in malpractice suits against its members and I should therefore assume that if you were going to undertake this work you would have to obtain an amendment to your charter"

That year (1921) the Massachusetts Medical Society recommended to its members that they take advantage of a group policy submitted by the United States Fidelity and Guaranty Company However, in 1923, the Attorney General (Jay K Benton) rendered an opinion that a group or blanket policy of liability insurance could not be issued to an association of dentists or physicians if the rates were discriminatory This opinion was written but not printed and has not been nullified The opinion was rendered because of complaints from the public that a cheaper rate was being given to physicians We were told by an assistant attorney general that there was nothing in the law to prevent medical societies from writing their own liability insurance Should the Massachusetts Medical Society undertake to do this, the assistant attorney general estimated that a surplus of about \$300,000 00 would be needed

III

REPLIES FROM INSURANCE COMPANIES

Most of the insurance companies to whom we wrote were co-operative. The Medical Protective Company, however, did not reply to either of our two letters

A. Eligibility Requirements

- (1) One company stated it was a strict requirement of their company that every doctor they insure be a member of the American Medical Association or any of its state or county associations.
- (2) One company stated that they did not accept all applicants. They may refuse to insure a graduate of an approved medical school and may accept a member who is a graduate of an unapproved medical school. However, they consider graduates of unapproved schools to be a much greater risk than those of approved schools. All applicants are investigated.
- (3) Three companies stated that they accept graduates of unapproved medical schools, two stated that as a rule they did not. No company stated that they would not accept a graduate of an unapproved school.

Comment: Some physicians, however, remarked on their questionnaires that they were unable to obtain malpractice insurance because they graduated from an unapproved medical school.

B. Co-operation with Committee of Society

All companies replying stated that they would co-operate with a committee of the Society. One company wrote, "We wholeheartedly welcome the opportunity of being able to co-operate with such a committee." The same company also stated that such a procedure would undoubtedly be an important factor in further reducing the cost of this protection to the members of the Society through the medium of favorable experience.

Another company suggested that if a member of a malpractice committee was in court and listened in every malpractice action in which adverse medical opinion evidence was to be given and made a complaint against any testimony that was untrue, that it would discourage such testimony. The company stated:

"The mere knowledge that such a committee would sit in at all malpractice trials would deter and discourage all physicians from giving testimony of dishonest nature, and this deterrent effect would be even greater if the State Board of Registration did the same thing. The weak, incompetent, and the mentally dishonest would hesitate more than they do now to risk their license for a prospective expert fee."

C. Rates in Massachusetts

- (1) United States Fidelity and Guaranty Company
\$10,000/\$30,000 = \$19.00-\$70.00
(depending on type of practice)
- (2) Hartford Accident and Indemnity Company
\$10,000/\$30,000 = \$25.00-\$74.00
(depending on type of practice)
- (3) American Motorists Insurance Company
\$5,000/\$15,000 = \$25.00-\$40.00
(depending on type of practice)
- (4) American Policyholders Insurance Company
\$10,000/\$30,000 = \$20.00 (same rate for both practitioners and surgeons) and after 1st year less 15% dividend or \$17.00 a year
- (5) Medical Protective Company
\$2,500/\$7,500 = \$17.00-\$23.00
(rates obtained from printed literature)

Comments: (1) Since the survey of malpractice insurance in Massachusetts has been in progress two companies have reduced their premiums.

- (a) The United States Fidelity and Guaranty Company reduced their rates 5 per cent for all specialties except x ray

- (b) The Medical Protective Company reduced their premiums from \$2.00 to \$3.00 on a policy

\$2,500/\$7,500 limits (restricted) from \$19.00 to \$17.00
\$2,500/\$7,500 limits (unrestricted) from \$25.00 to \$23.00
\$5,000/\$15,000 limits (restricted) from \$22.00 to \$19.00
\$5,000/\$15,000 limits (unrestricted) from \$30.00 to \$28.00

- (2) Of the various companies investigated the American Policyholders Insurance Company, a subsidiary of the American Mutual Liability Insurance Company, offered the most attractive rates. Their policy is comparable to those of the other companies. Also,

- (a) They will insure all members of the Massachusetts Medical Society. They consider membership in the Society a sufficient recommendation.
- (b) Their basic rate applies to all physicians — both general practitioners and specialists only those giving x ray treatment and doing cosmetic plastic surgery have to pay a higher rate.
- (c) They will co-operate 100 per cent with a committee of the Society.
- (d) They will use the attorneys recommended by the Society.

IV

ADDITIONAL DATA

Incidence of Malpractice Suits

Robert Winston Smith of Boston in a series of articles entitled "Legal Responsibility for Medical Malpractice" which appeared in the *J. A. M. A.* during 1941 stated "Much is heard and said about the peril of malpractice claims but there is a definite lack of accurate information by which one might appraise the reality and size of this hazard." In an effort to obtain some factual data Smith collected and tabulated all the civil malpractice appeal cases decided by American courts from 1794 to January 1, 1940. In the following table is presented the appeal cases from 1930 to 1940.

INCIDENCE OF APPEAL CASES OF CIVIL MALPRACTICE

According to Population and Number of Physicians

State or Jurisdiction	Total Cases (1930 to 1940)		Cases per Million Population (1930 to 1940)		Cases per Physician (1930 to 1940)	
	No.	Ratio	No.	Ratio	No.	Ratio

Wisconsin	11	17	3 759	27	0 0032	28
Wyoming	2	41	8 510	8	0 0076	7

Comment The cases decided by the appellate courts obviously represent only a fraction of the complaints of negligent practice. The appeal cases are those which usually involve a substantial "stake" — judgments ranging from \$1000 to \$50,000

Massachusetts with eighteen appeal cases between 1930 and 1940, was rated sixth, in other words, only five states had more such cases. On the other hand, in so far as cases per million population are concerned (4 067), Massachusetts was 25 and with 0 0024 cases per physician, Massachusetts was rated 34 — only fifteen states had less cases per physician

CONCLUSIONS

- (1) More information on the subject of malpractice insurance should be accumulated
- (2) After sufficient data have been collected, the advisability of adopting a group-type of insurance should be considered.

RECOMMENDATIONS

- (1) That the Massachusetts Medical Society should not undertake its own liability insurance at this time
- (2) That no one company be recommended exclusively at this time.
- (3) That a special committee of five fellows be appointed by the President to act in an advisory capacity to the Society and insurance companies in regard to malpractice insurance
- (4) That the present committee be discharged

APPENDIX NO 6

REPORT OF THE COMMITTEE TO ESTABLISH A PENSION PLAN

The problem before the committee was to arrive at some principles to be followed in establishing a pension plan for the employees of the Massachusetts Medical Society. Dr Robert N Nye, managing editor of the *New England Journal of Medicine*, was made a member of the committee in order to facilitate the adoption of any plan that might include employees of both the Massachusetts Medical Society and the *New England Journal of Medicine*

There are now nineteen employees, seven of whom work for the Massachusetts Medical Society and twelve who are employed by the *Journal*

The following points had to be considered

Who is to be included?

What amount is to be paid at retirement?

When shall the benefits be payable? (An employee will do only one of three things retire, die or resign. If the benefits accruing under these occurrences are determined, each activity of the employee is covered.) Shall the employee contribute?

Who Is To Be Included?

Probationary period It is essential that a probationary period be established before eligibility. Should this be one, two, three or five years? We recommend five years.

Participating age Little interest in a plan to benefit them at age sixty-five can be expected from young girls. Most of them do not expect to stay, and generally any money spent for them is wasted. What age for participation of employees shall be established? Should this be twenty-five, thirty or thirty-five? We recommend age thirty-five for women and thirty for men.

Minimum years of service It seems reasonable that if an employee is first employed by the Society late in life, the Society does not have an obligation to provide a pension for that employee. Another way to express this thought is: What is the minimum number of years of service that should determine whether an employee is entitled to a pension — should this be ten, fifteen, twenty or twenty-five years? We recommend twenty years.

What Amount of Retirement Income Is To Be Paid?

Many plans give a pension credit for each year of service, generally 1 per cent or a fraction thereof for each year of service to date (past service) and 1 per cent for each year of future service. If the employee has many years of service, this provides a good pension, but this would not produce a pension commensurate with earnings for our top-salaried people. For example

A female employee, age fifty-five, employed twenty-seven years, now earning \$4500 yearly, would be asked to retire on \$140 monthly, the equivalent of \$30 weekly, after thirty-seven years of service.

A female employee, age fifty-two, employed twenty years, now earning \$2500 yearly, would be asked to retire on about \$70 monthly, the equivalent of \$15 weekly, after thirty-five years of service.

A male employee, age fifty-five, employed ten years, now earning \$10,000 yearly, would be asked to retire on about \$170 monthly, the equivalent of less than \$40 weekly, after twenty years of service.

A male employee, age fifty-seven, employed twelve years, now earning \$4800 yearly, would be asked to retire on about \$88 monthly, the equivalent of less than \$20 weekly after twenty years of service.

We recommend that a pension of 50 per cent of the salary at the time the insurance is written be provided as a goal. If the recipient is granted increase in wages between the time he becomes eligible and the time he reaches the retirement age, proportionate increases in benefits would be added to the terms of the policy, but, in no case, irrespective of the wage at the time the policy is written, is the final monthly pension payment to be more than \$200.

When Shall the Pension Benefits Be Paid?

Retirement age Shall retirement be at fifty-five, sixty or sixty-five? The longer the period of funding, the smaller annual amount is required, also, the amount needed to buy a pension for an employee age sixty-five is less than for a pension at age sixty. Our recommendation is age sixty-five.

Death Certainly the Society does not want to profit by the death of an employee, accordingly we recommend that whatever death benefit is available under the annuity contract be paid over to the beneficiary of the employee.

Disability or early retirement. If the employee withdraws within five years of membership (ten years of service), he receives on part of the annuity if he leaves after five years of membership, he is entitled to 25 per cent of the annuity already purchased, the balance goes to the Society. The amount he receives increases thereafter. He may receive this either in the form of cash (the proper percentage of the cash value of the annuity) or in the form of an annuity (that percentage purchased at the time of disability or early retirement) to be paid by the insurance company when he reaches retirement age (sixty five).

Shall the Employee Contribute?

This is a matter of personal opinion. The persons to be covered under our recommendations would appear to be able to make some contribution, but it is our recommendation that such an amount as they may elect to contribute should be used for the purchase of increased annuity rather than to decrease the amount paid by the Society for the basic annuity.

Summary of Recommendations

Eligibility. Those employees age thirty if male and thirty five if female, who have been in our employ five years or more and who at retirement will have had twenty years service.

Retirement pension. Fifty per cent salary at the time the insurance is written.

Death benefits. Full amount, as provided by the insurance company.

Termination-of-service benefits. Prior to first five years none; five to nine years, 25 per cent; ten to fourteen years 50 per cent; and fifteen years or more, 100 per cent.

With the above recommendations in mind it is found on looking over the seven employees of the Massachusetts Medical Society that only one—a man aged fifty-seven years—is eligible. The others are either under participation age or have not been in our employ for a sufficient period of time. This being the case the simplest solution would seem to be to make no attempt to establish a program of group insurance and retirement.

Your committee recommends that no individual contract be made for this employee in the cost of which he may participate to whatever extent he wishes and that the selection of the company be made on the basis of both his wishes and those of the Treasurer of the Society. We have data from several companies concerning the cost of this type of retirement plan. It is suggested that this method might well be followed in each individual case as the person becomes eligible for insurance and a pension. It is further suggested that the individual arrangement be made by the Treasurer of the Society.

As an illustration of the probable cost of a typical retirement policy the annual rates of four companies on the basis of \$100 of pension are as follows:

Age 35	\$ 411 20 to	500 60
Age 45	679 10 to	817 00
Age 55	1 488 00 to	1 746 40

In view of the above data the committee recommends that no fund be established at the present time for the purpose of providing insurance and pensions for employees, but that individual arrangements be made as the occasion arises.

APPENDIX NO 7

REPORT OF THE ADVISORY COMMITTEE ON SCHOOL MEDICAL SERVICES

The Committee on School Medical Services appointed by the Council on February 5, 1947, to "establish an effective liaison between representatives of the Massachusetts Medical

Society and health and education officials on both state and local levels" submits the following informational report together with certain recommendations.

For the information of the Council—

(1) On May 23, 1947, your committee met with Mr. Arthur Pierce, superintendent of schools of Wellesley, appointed by the Massachusetts School Superintendents' Association to be the liaison person between the Superintendents' organization and your committee.

(2) Your committee submits for your information this copy of a letter being sent to all district society secretaries requesting the submission of physicians' names to be appointed to the district committees on school medical services.

(3) The Council referred to this committee the following recommendation of the Committee on Public Health: "That the Massachusetts Medical Society approve suggested legislation providing for full time qualified medical health officers whenever possible and that school medical service be under their direction. The remuneration for full time medical health officers should be sufficient to attract qualified personnel." A consideration of this recommendation led to so much discussion that it was decided to table this for the present, to allow for further information and discussion.

(4) The Council referred the following recommendation to the committee: "Examination by a private physician be acceptable to the school medical authorities if the examination is recorded on the school health form." Your committee changed this to read, "Examination by a licensed private physician be acceptable to the school medical authorities if the examination is recorded on the school health record form." This point was referred to the Commissioner of Public Health and Dr. Gettling replied that he did not think this should be made the subject of a formal opinion by the Attorney General's Office on this point of law. It was Dr. Gettling's opinion to which the Assistant Attorney General Roger Clapp concurred that "It would be entirely within the province of a school department to accept a medical examination by a licensed physician."

(5) The Council referred the following recommendation to the attention of this committee—"That teacher training be provided to teachers' colleges to grow and development of children in teacher observation of the health of children and in health education." This recommendation led to a great deal of discussion and the matter was tabled with the suggestion that a subcommittee of this committee and educators be appointed to make a further study and submit recommendations concerning teacher training to the field of health.

(6) The Council referred the following recommendation to this committee—"The State Dental Society be encouraged to participate in the school health program to a greater extent." Your committee changed this to read, "The committee would pursue the co-operation between the medical and dental societies in the school health program."

Your committee accepts the following three recommendations unchanged.

(7) "That qualified district and community nutritionists provide for nutrition phases of local school health programs including school lunch programs."

(8) "That there be provided adequate physical, mental and psychological examinations of entering school children early enough so that there may be correction of remediable defects and completion of immunizations before the child enters school."

(9) "That the presence of parents be urged at the examination of younger children so that parental understanding of health needs may be insured."

(10) Your committee changed the following recommendation—"That the interpretation be provided by the school physician and nurse of health findings to older children so that they may be motivated to do what is in their power to improve their health" to read "The interpretation to be provided by the school physician and the nurse, acting under his supervision of health findings to older children so that they might be motivated to do what is in their power to improve their health."

(11) Your committee changed the following recommendation—"That there be provided interpretation by the school physician and nurse of health findings to teachers so that they may understand the health status of children under their daily observation" to read "That there be provided interpretation by the school physician and nurse of health findings to teachers so that they may assist the school nurse in emphasizing conditions to

parents" to read "To be provided by the school physician and the nurse under the guidance of the school physician, the interpretation of health findings to teachers so that they may understand the health status of children under their daily observation, may make suitable provisions in classrooms and may assist the school nurse in emphasizing conditions to parents."

(12) Your committee changed the following recommendation — "That there be co-operation with the physical education program" to read, "The physical education program is an integral part of the over-all health program and should be worked out co-operatively with the school health authorities."

(13) Your committee changed the following recommendation — "That continuing staff education for health personnel be provided under suitable auspices" to read, "continuing staff education for public health personnel should be encouraged."

RECOMMENDATIONS

(1) Your committee recommends that the present law requiring annual examinations be amended to provide for less frequent, but more adequate examinations on a spaced and selective system at least four times during the child's normal school life.

(Your committee suggests that the Executive Committee arrange with the Legislative Committee and Dr. Conlin and others authorized to draw up such a bill and present it to the Council at its October meeting. Mr. Pierce offered to secure approval of the Massachusetts Superintendents' Association through Mr. Burr Merriam and of the Massachusetts Teachers Federation through Mr. Hugh Nixon. He suggested that the Massachusetts Women's League and the League of Women Voters be asked to support the bill.)

(The opinion of the Commissioner of Public Health was sought to see if an "adequate" examination included the disrobing of children. Dr. Getting's opinion in which the Assistant Attorney General, Roger Clapp, concurred was "that the disrobing of children is necessary if an adequate physical examination is to be made.")

(2) The American Medical Association is sponsoring a conference on the Co-operation of the Physician in the School Health and Physical Education Program, October 16-18, 1947, under the auspices of its Bureau on Health Education. The conference will be held at the Hotel Moraine, Highland Park, Illinois. Invitations to send representatives will be extended to state medical societies (one representative from each state), state departments of education, health, teacher education and education administration (one from each state).

Dr. O'Hara referred the invitation to the Committee on School Medical Services with the notation that in his opinion the Massachusetts Medical Society should be represented and that this committee should ask for an extraordinary appropriation at the October meeting to cover the expenses of such representation.

Your committee considered the invitation and agreed that the Massachusetts Medical Society should be represented by a member of the Committee on School Medical Services and that either the chairman or Dr. Morris might be able to attend.

Your committee, therefore, recommends that the Council approve such representation and grant an extraordinary appropriation to cover the expenses of the trip.

APPENDIX NO 8

REPORT OF THE MASSACHUSETTS REPRESENTATIVES TO THE HOUSE OF DELEGATES OF THE AMERICAN MEDICAL ASSOCIATION, ATLANTIC CITY, JUNE 9, 10, 11 AND 12, 1947

The meeting of the House of Delegates opened promptly at 10 a m., June 9, 1947. Out of a total of 175 delegates avail-

able, 173 delegates indicated their presence — an excellent showing. Five of your delegates were present: David D. Scannell, Leland S. McKittrick, Charles J. Kickham, Allen G. Rice (alternate for Charles E. Mongan) and John I. B. Vail (alternate for Walter G. Phippen). The first business of the meeting was the balloting for the recipient of the Distinguished Service Award. Two surviving out of three names were those of Dr. Henry A. Christian and Dr. Isaac A. Abt of Chicago. The Christian vote was 100, Abt's, 73. Although notified at once of his selection, Dr. Christian was unable to be present the following evening to receive the award in person.

There followed the usual addresses of the Speaker, the President and the President-Elect. All these addresses were of a very high quality and deserve to be read as they appear in the *Journal of the American Medical Association*, June 21 and later. We wish to call attention to the addresses of President Bortz on the morning of the first day and on the evening of the second day when he was inducted into office. They were unusually thoughtful and timely.

Following this, came the reports of the officers, many of them by title, since the delegates had read them in the handbooks issued several weeks before the meeting. Excellent addresses followed by Major-General Raymond D. Bliss, Surgeon-General of the United States Army (successor to General Kirk) and Rear-Admiral Clifford A. Swanson (successor to Admiral Ross McIntyre).

Assignments were then made to the various committees, which on this occasion concerned our group very little. We wish here to repeat what we have stated on many previous occasions: membership on these reference committees is the hardest kind of work — under pressure and under debate. This time it was harder than ever because of the multiplicity of measures introduced, requiring an unusual amount of deliberation. One thing that slowed up the meeting of the House was the introduction of foreign visitors and the reading of congratulatory messages from all over the world. There were present more than fifty visitors from foreign countries and at least twenty-five or thirty were presented during the first two days, some merely taking a bow, but many choosing to pay verbal compliments on the centennial of the Association. One speaker appearing on this first day was Admiral Boone whom we heard in San Francisco in July, 1946, on the same subject, viz., "Health Conditions in the Soft Coal Industry." He is an admirable speaker, clear-headed, convincing and brief. This time, as last, he made a very strong impression. The Government is most fortunate in having such a man in its service. His address should be read (Page 714 in the *Journal of the American Medical Association*, June 21).

One of the most important reference committee reports was submitted on the second day. This came from the year-old Interim Committee on Executive Session, appointed in San Francisco in 1946, this committee had rendered its first report on the Rich Associates in Chicago in 1946 and had been continued for further study. The Committee consisted of Bates of Pennsylvania, Buntz of Georgia, Carey of Texas, Hein of Ohio, Lewis of New Jersey, McGlendon of California, and Scannell of Massachusetts. The matters at issue were public relations and the association of the American Medical Association with the National Physicians Association. The Reference Committee, after long study and considerable expense, brought in a report completely justifying the liaison or co-operation with the National Physicians Association, concluding by recommending that a change be made in the public relations consultant of the American Medical Association. As a matter of fact, the Rich Associates through Mr. Rich himself and the newly appointed Executive to the General Manager, Mr. Swart, anticipating our report, resigned even before our report was made to the House of Delegates. Our report was unanimously approved and the committee discharged.

At the dinner meeting given that evening to the House of Delegates by the Trustees, there was presented by a member of the Postmaster-General's Department the new stamp commemorating the Centennial of the American Medical Association. This is an unusual stamp and of particular significance. The ninety million stamps issued to the Atlantic City visitors were, I believe, all sold on the fifth day of the convention (many visitors taking sheets of 500-1000 of these beautiful

three-cent stamps) They portray the doctor at the bedside of the sick child with the peasant parents near by.

All through the meeting, in the reports of officers, reference committees, and other addresses, emphasis was placed on the general practitioner his important place in the community and the necessity for helping him in all ways, especially with scientific exhibits. This came to a climax when on the last day of the meeting of the House of Delegates it was decided to hold the supplementary or mid winter meeting of the House in different centers each year (instead of in Chicago as heretofore) followed by a two-day scientific exhibit for the general practitioner only. This gives the answer to those who have insisted that the day of the general practitioner is done. This is an epochal event and one of the most important moves the American Medical Association has ever made.

There is much profitable reading in the pages of the *Journal* with reference to this centennial meeting; this is to be found in the issues of June 21, 28 and July 1. Especially worth while are the reports of the councils on Medical Education and Hospitals, National Emergency Medical Service, Medical Service and so forth.

On the second morning short addresses were made by various visiting guests particularly those from England, Iceland, Australia, Denmark, Syria, Cuba, Venezuela, Guatemala, Canada, Switzerland, Mexico, Colombia, China, Argentina, Norway, Hungary, Saudi Arabia, Panama, Belgium, Sweden and Finland. Various resolutions having to do with the specialty boards and their policies were introduced and freely discussed. Most important was the supplementary report of the Council on Medical Education and Hospitals, which we believe should be presented in full. The report is as follows:

MR. SPEAKER. The Council on Medical Education and Hospitals has directed me to introduce the following supplementary report:

Considerable thought has been given to devise ways of upholding the prestige of general practitioners so that they may be encouraged to provide the citizens of our country with the kind of medical care which they are peculiarly qualified to furnish and for which there promises to be continued need.

The establishment of a Section on the General Practice of Medicine by this House in 1945 was an important step forward. Interest in this section was at once apparent as shown by a registration of 939 at the 1946 Scientific Assembly and by the attendance of these registrants at the various meetings. This House has also expressed its approval of the organization of sections on general practice in state and county medical societies.

In spite of this, certain hospitals have inaugurated as a matter of policy limitation of their staff appointments to physicians certified by specialty boards or holding membership in certain medical societies. Such a policy is contrary to the principles of the Council and seems anomalous. In publications which have dealt with hospital standards the Council has expressed repeatedly the need for a hospital staff of high quality; it has never mentioned certification by a specialty board or membership in a special medical society as an important credential.

Certain institutions have assured for themselves the inclusion on their staffs of properly qualified general practitioners by the intramural establishment of "General Practice Sections". An excellent description of how such a section actually operated over a period of eight years in a 450 bed hospital appeared on pages 15 through 16 of the May 3, 1947, issue of the *Journal of the American Medical Association*. Reprints of this article will be distributed by the Council to every registered hospital in the United States.

On the whole, so much uncertainty appeared to exist in the minds of many boards of trustees of hospitals about the propriety of establishing such sections as to lead this House at its meeting in San Francisco a year ago to adopt a significant resolution. This was reported favorably by the Reference Committee on Medical Education and adopted by the House. Part of this resolution is quoted

"WHEREAS Many hospitals have not established general practice sections in their visiting active staffs and their governing heads are doubtful whether such action has the

approval of the bodies which set up the rules and regulations for the approval of their hospitals for interns and residents, therefore be it

Resolved, That hospitals should be encouraged to establish general practitioner services. Appointments to a general practice section shall be made by the hospital authorities on the merits and training of the physician. Such a general practice section shall not prevent approval of a hospital for training of interns and for residencies. The criterion of whether a physician may be a member of a hospital staff should not be dependent on certification by the various specialty boards or membership in special societies.

Copies of this resolution have been sent to the American College of Surgeons, the American College of Physicians, the American Hospital Association, the Protestant Hospital Association, the Catholic Hospital Association and to each hospital registered by the Council.

To carry forward the intent of the resolution the following report was published by the Council in *The Journal*, page 95 in the May 3, 1947 issue:

At the direction of the House of Delegates of the American Medical Association some years ago, the Council on Medical Education and Hospitals formulated standards for the establishment of American boards for the certification of specialists and for the conduct of hospital residencies providing training in the various special fields of medicine. The aim was to improve the quality of training at this level of medical education. The physician responsible for directing such hospital training should himself have had training and experience approximately equivalent to that required of certification applicants whether or not he is actually certified. But it was never intended that staff appointments in hospitals generally or even in hospitals approved for residencies should be limited to board certified physicians, as is now the policy in some hospitals. Such policies if practiced extensively are detrimental to the health of the people and therefore, to American medicine. Hospital staff appointments should depend on the qualifications of physicians to render proper care to hospitalized patients as judged by the professional staff of the hospital, and not on certification or special society memberships.

In this opinion the Council has the full concurrence of the Advisory Board for Medical Specialties which represents all the American Boards in the specialties. At the February 1947 meetings of the Advisory Board it was unanimously voted to adopt as the sentiment and policy of the Advisory Board the recent resolution passed by the American Board of Surgery which reads:

The American Board of Surgery is not concerned with measures that might gain special privileges or recognition for its certificants in the practice of surgery. It is neither the intent nor has it been the purpose of the Board of Surgery to define requirements for membership on the staffs of hospitals. The prime object of the Board is to pass judgment on the education and training of broadly competent and responsible surgeons—not who shall or shall not perform surgical operations. The Board specifically disclaims interest in or recognition of differential emoluments that may be based on certification.

Since February several separate American Boards in the various specialties have taken similar action. The Council on Medical Education and Hospitals of the American Medical Association is completely in accord with this principle.

The Council now asks authority to use still another level to carry forward the intent of the resolution. It recommends that Section 3 paragraph 6 of the "Essentials of a Registered Hospital" now reading:

"6. Staff sections, such as medicine, obstetrics and surgery should be organized as may seem wise
be amended to read

6 Staff sections such as medicine, obstetrics, surgery, general practice, etc., should be organized as may seem wise

This amendment is proposed in the belief that even so small a change in words of the Essentials may be of help in promoting the intent of the resolution adopted by this House a year ago.

The desirability of doing this is plain. The establishment of an American Board of General Practice is being discussed by the Section on the General Practice of Medicine, by the Council and by the Advisory Board for Medical Specialties. The wisdom of establishing such a specialty board at this particular time is debatable. Wider realization and greater use of the contributions which skillful general practitioners can bring to hospitals may make superfluous the need for their certification by a specialty board.

Also discussed at length in the report of the Board of Trustees was the formation of a World Medical Association. At a preliminary meeting held some weeks ago, Drs. Bauer and Henderson representing the American Medical Association went to London, and they, with Dr. Irons, are to represent the Association at a meeting to be held a little later this year in London. This would seem to be the opportunity and responsibility of the American Medical Association to assist in the development of a world medical front in meeting problems as they develop in the councils of world health organizations and in the divisions of the United Nations.

Simultaneously, there is groundwork being done for a Pan-American Medical Federation. Here, also, much work has been done by three members of the American Medical Association in connection with members from Canada and Central and South America. A fairly long plea for this Pan-American Federation was presented by the delegate of the Pan-American Congress from Cuba, his proposals can be found on Page 796 of *The Journal*, June 28.

At the inter-session luncheon of the House of Delegates Tuesday, June 10, excellent addresses were made by Secretary of War, Robert P. Patterson and Assistant Secretary of Navy for Air, John N. Brown. Secretary Patterson's speech was so important that we believe it should be incorporated in this report and later printed as a separate article in the *New England Journal of Medicine*. Some of the measures he proposes chart a new policy in a governmental agency to provide medical care in peacetime. The reading of this report is a "must" and is as follows:

Your consideration in inviting me here this afternoon to discuss the Army Medical Corps' pressing problem is a courtesy that I appreciate very much.

You are a busy group, with many important questions to discuss, so I shall get right down to the facts. However, I do want to take time to repeat the statement that I made this morning before the General Scientific Meeting:

"The medical service of the American Army in World War II was the finest of any Army in the world."

It is one thing to express a determination on the Army's part to maintain its medical service on a par with that provided from 1941 to 1946. It is quite another thing to recruit in peacetime the number and type of physicians that a medical service of this high quality requires.

The motive of patriotic self-sacrifice that led forty-seven thousand of the medical profession to volunteer their services in war cannot be depended on today to provide the necessary physicians for the Army. It is not to be expected that it should. The fact remains, however, that the Army must continue to count on the patriotism of the medical profession in other ways than direct service. Your continued interest in the Medical Department, your co-operation and your support are necessary. Without them no program can be successful.

I need not labor the point that in these troubled times the Army is indispensable to our national safety. Most of our soldiers are on active service overseas, chiefly in Germany, Austria, Japan and Korea. They are keeping the peace, with the result that we may meet here without excursions and alarms. But the Army cannot be strong unless we have a strong medical service. The predicament of the War Department in getting medical

officers is therefore a matter of patriotic concern to the whole medical profession. If there is a matter of greater urgency, I do not know what it is.

Present plans of the War Department call for an Army of 1,070,000 men. We shall need an Army of more or less that size so long as we have our present commitments for occupation abroad and national security at home.

Six thousand doctors are required to provide adequate medical service for an army of 1,070,000 strength. At present we have five thousand doctors in the Medical Corps. However, only eleven hundred of these are in the Regular Army. If the present state of national emergency were to be terminated we would lose all our doctors except those in the Regular Army. Even if the emergency remains in effect, the younger officers now on temporary service will be leaving in large numbers on expiration of their two years' service. Unless prompt measures are taken, the prospects are that we will be short thirty-seven hundred doctors by mid-year of 1949, and short forty-four hundred doctors, or more than two thirds of our requirement, by mid-year 1950.

We must therefore make every effort to induce as many as possible of these officers to volunteer for further duty in the Medical Corps, and we must also actively recruit physicians from civilian life.

To date the results of our efforts to build up our professional medical personnel have been disappointing. The response to the invitation to medical officers on temporary duty to become part of the Regular Army fell far below expectations.

There are many reasons why medical officers of the Army of the United States — the A U S — did not respond to the invitation to become part of the Regular Army. I do not propose to go into those reasons. We know them, and you know them. Through the work of the Secretary of War's Medical Advisory Committee that I asked to help the War Department on its medical program, those reasons were compiled and presented to the Army in a way that required the Army to do something by way of cure.

The Army is going to do something about it. We have already begun — and we intend to continue, with your help, until we have solved the problem. A major step in our program to provide a professionally competent and adequate medical service for the Army is the introduction in Congress of legislation to "provide for the procurement of physicians and surgeons in the Medical Department of the Army." That legislation is identified in the House of Representatives as H. R. 3174, and in the Senate as S. 1143.

At a casual reading of the bill, it would seem that the principal purpose of that legislation is to provide more pay for medical officers. Such a conclusion would confuse the means with the end. The actual purpose of that bill is to promote and enhance the professional standing of the Army Medical Corps.

The War Department is convinced, after more than one hundred and seventy years of close association with the medical profession, that the skill of the American medical man cannot be bought for dollars and cents. But it is given generously as a matter of patriotism and professional pride. The doctor can have such a pride in the Army medical service only when that service has the highest possible professional dignity. I am already on record with the statement made last year that it is my sincere desire to maintain the medical standards of the Army at the highest possible professional level. I want now to reiterate that statement as expressing both the Army's and my determination. General Eisenhower also expressed the Army's position when, in a memorandum to the Army's top commanders, he said:

The realization of our objective places upon us, the military, the challenge to make our professional officers the equal in knowledge and training of civilians in similar fields and make our professional environment as inviting as those outside.

The War Department knows that a medical service equal to the needs of our modern Army can be obtained and continued only by establishing a professional level

equal to the best in civilian practice. Establishment of that professional level is our goal. All other advances benefits or gains serve only as steps toward that goal.

Yet, we intend to be practical in seeking our objective. We realize that no governmental agency can hope to give to the doctors who will serve it a direct financial return equal to what the best men in the profession can make in civilian life. At the same time, we cannot expect and do not intend to ask competent doctors to devote their years to the Army without compensation that at least is worthy of the important position they hold and adequate for their needs.

The legislation now before Congress is our answer to that part of the problem and for that reason I want to go over it with you. It must have your support, not only to win Congressional approval, but to serve its purpose—the improvement of the professional status of the medical officer.

The first part of the bill would give to all Medical Corps officers with less than thirty years service \$100 a month extra pay. The increase would apply both to regular officers and to nonregular officers who volunteer for extended active duty for a period of one year or longer.

The next three sections of the bill are the basis of our efforts to improve the professional status of the Medical Corps. Two of these sections also deal with specialists, and they are of great importance. The quality of medical care will be determined by fulfillment of our needs for surgical and medical specialists. These we must have if we are to provide the Army with a high standard of professional care.

About thirty per cent, or eighteen hundred, of the six thousand medical officers required for the Army of the present strength should be specialists. So far, we have about one fifth of that total, including those in retraining. In obtaining sufficient specialists, the Army is handicapped not only by the small pay in comparison with earnings in civilian practice, but also by the competition of other Government agencies paying more than the Army presently is authorized to pay.

Titles II and IV of the bill now in Congress would do much to improve the Army's position in retaining and obtaining specialists for the Medical Corps.

Title II provides for an increase of 25 per cent in the base and longevity pay of those Medical Corps officers who qualify as specialists, during the time such officers are so qualified. Certification of a recognized American as a Specialty Board would be required for qualification as a specialist in the Medical Corps but all Medical Corps officers, regular and non regular alike, would be eligible to qualify. The Veterans Administration already has the right to make such extra payments to its specialists.

Title IV of the proposed legislation would permit the Army to make original appointments of outstanding medical specialists in the Medical Corps from civilian life, in grades and ages above those to which such appointments now can be made. Under the bill appointments as specialists could be made in any grade up to and including colonel, the grade for each appointee being determined by his qualifications. Doctors thus commissioned from civilian life would be only those certified as specialists by a recognized American Specialty Board. In the past statutory limitations prevented our commissioning such officers at grades commensurate with their abilities. As a result, we were unable to obtain the services of specialists even though they were available.

If the Medical Corps is to attract physicians through the opportunities it offers for professional work of high quality it is obvious that within the Corps there must be men in key positions who set the standards for professional work and guide the careers of young medical officers. To provide such advisers to the Surgeon General, the Bill, under the provisions of Title III authorizes the direct appointment in the grade of brigadier or major general of four physicians distinguished respectively in the fields of medicine, surgery, neuropsychiatry and preventive medicine. The mission of these leaders would be to supervise professional standards, educational programs and the assignments of professionally qualified

officers. They will carry in addition to their rank, the titles of professors.

Appointments to the four professorships would be made by the President of the United States, with the consent of the Senate.

The Army Medical Department hopes to meet its responsibilities with commissioned personnel. However, if we are unable to procure the necessary military personnel we must be able to utilize the services of civilian doctors. Title V of the new bill will give us the necessary authority. It will permit the appointment of civilian physicians, in such numbers and for such periods of time as may be necessary, without regard to Civil Service requirements, and is substantially identical with the authorization given some eighteen months ago to the Veterans Administration.

Properly qualified civilian doctors would be appointed under this legislation in one of six grades, the annual pay scale of which would range from \$3640-\$4300 for junior grade up to \$8750-\$9800 for chief grade. Further, if a civilian doctor thus appointed is designated a specialist, he would receive an allowance equal to 25 per cent of his base pay up to a total of \$11,000 a year.

Employment of civilian physicians on a temporary full time, part time or fee basis also would be authorized by this legislation.

These five sections sum up the legislation now before Congress to improve the professional status of the Army Medical Corps. They are in the opinion of the War Department the best answer to the problem of procuring qualified medical officers.

Other plans were considered and found wanting. These included subsidization of the education of prospective Medical Corps Officers and establishment of an Army medical school. Still other recommendations and suggestions for improving the Army medical service are being studied seriously.

The basic need of an adequate Army medical service is a professional competence second to none. The legislation now before Congress is designed to go a long way toward making that high grade professional attainment possible. The War Department will do everything else in its power to establish and foster the professional environment required. I ask your support of this legislation and of our entire Medical Corps program.

The meeting lasted four full days' mornings and afternoons. As a result, very few members of the House of Delegates had an opportunity to visit the scientific exhibit by all odds the best ever presented. Likewise, the commercial exhibit was a remarkable piece of organization. Obviously the opportunity for listening to valuable papers on clinical and basic scientific subjects did not exist for the delegates. In short the four-day session for the House of Delegates was *uninterrupted work*. On the final afternoon (Thursday) the following were the highlights:

1. The election of Dr. Sensemich as president-elect.
2. The election to the Board of Trustees of Dr. E. J. McCormick of Toledo. He is a hard worker and as coo-selections a delegate as the American Medical Association possesses.
3. The change in locale of the annual meeting of the American Medical Association for 1948, 1949 and 1950. In 1948 the change will be to Chicago instead of St. Louis. In 1949, Atlantic City instead of New York. In 1950 it will be San Francisco.
4. The supplementary meeting of the House of Delegates in mid winter not necessarily to be held in Chicago but in various centers changed each year. Two-day sessions to be followed (as stated previously) by two-day scientific exhibit for the general practitioner. Name of the place for the December 1947, meeting has not yet been determined.
5. To conclude the meeting of the House of Delegates was a most satisfactory one although rather too long drawn-out for reasons given above. The great number of resolutions introduced were fairly and patiently considered and we feel certain as we have in years past that once again our opinion was confirmed by all our foreign guests who spoke on the subject.

DAVID D. SCAMMELL

APPENDIX NO 9

COMMITTEE TO STUDY SPECIAL SERVICES

This committee has been asked to define hospital services and medical services and to establish the proper relations between physicians and hospitals.

To gain as accurate an appraisal as possible of the sentiments of the physicians of the Commonwealth on these important problems, a post card was sent to the 6000 participating Blue Shield physicians, requesting their opinion. Fifty-one replies were received. Thirty-four of these expressed the belief that nonmedical hospital services and medical hospital services should be strictly separated. None opposed this separation. Of the remaining 17, the majority complained of their exclusion from hospital staffs and seemed to believe that the solution of this problem constituted part of the committee's function. Although the committee is sympathetic with physicians who are faced with this problem, it considers the problem to be outside the scope of its activities and not implied in the order of the Council establishing its duties.

In attempting its task the committee is well aware of the fact that conditions may properly vary in different localities and in different institutions, that the practice of medicine is undergoing rapid changes under unusual stresses, and that the concepts of tomorrow may vary markedly from those of today.

There are, however, certain fundamental principles that should not change if the profession of medicine is to discharge its obligation to society on an increasingly high level.

First, we accept the principle that the primary object of medical practice is to deliver the best possible care to the patient. Second, we believe that this objective can best be attained by an independent and unfettered profession, conscious of its ideals and its responsibilities.

These principles are basically defined in Chapter III, Article VI, Section 5, of the *Principles of Medical Ethics of the American Medical Association*.

It is unprofessional for a physician to dispose of his professional attainments or services to any lay body, organization, group or individual, by whatever name called, or however organized, under terms or conditions which permit a direct profit from the fees, salary or compensation received to accrue to the lay body or individual employing him. Such a procedure is beneath the dignity of professional practice, is unfair competition with the profession at large, is harmful alike to the profession of medicine and the welfare of the people, and is against sound public policy.

Nothing in this report refers to interns, residents or fellows. The committee is aware that this problem deserves separate consideration.

In accordance with these principles the committee submits the following definitions and recommendations.

SERVICES RENDERED IN HOSPITALS

Nonmedical Hospital Services

Nonmedical hospital services are defined as those services, technical and nontechnical, provided by other than a registered physician, which are required for the care of patients, the making of a diagnosis and the treatment and prevention of disease, and those services rendered by a registered physician in an administrative capacity or as the head of a department when such services do not include the obtaining or interpretation of information in behalf of an individual patient.

These shall be considered to include the following: administration, nursing, social service, record room and library, pharmacy, dietary service, housekeeping and laundry, main-

tenance of building and grounds, including the provision, maintenance, repair and replacement of technical equipment and supplies, provision of technical and nontechnical personnel and their qualified supervision, reports without interpretation from the clinical laboratories, and such other services as may be necessary for the operation of a hospital.

Medical Hospital Services

Medical hospital services are defined as services other than administrative, rendered by a registered physician directly or indirectly to or in behalf of an individual patient for the obtainment and interpretation of data, including consultation and advice, for the diagnosis, treatment and prevention of disease. Such services will embrace the general and special practice of medicine, surgery and obstetrics, and the practice of the related specialties including anesthesiology, physical medicine, radiology, pathology and clinical pathology including bacteriology, clinical chemistry and other clinical laboratory specialties.

It is accepted as a basic principle of good medical practice that a professional interpretation should accompany the report on radiologic examinations and on materials and tissues examined by the pathologist.

ESTABLISHMENT OF PROPER RELATIONS BETWEEN PHYSICIANS AND HOSPITALS

To establish principles governing the proper relations between physicians and hospitals, your committee makes the following recommendations:

That the medical costs of hospital care be separated from the nonmedical costs, as can be done by existing and accepted methods of cost-accounting, and that they appear thus separated on the statement submitted to the patient.

That bills for all medical services be rendered in the name of the physician or physicians performing the services.

That a basic principle in the establishment of charges should be that each department be self-supporting. This principle should be so applied that neither the hospital nor the physician rendering the service will exploit the patient or each other.

That fees for medical services collected by the hospital be established by joint action of a representative committee of the staff and the governing body of the hospital and including also the head of the department and the administrator.

That the basis of financial arrangement between hospital and physician may be salary, commission, fees, or such other method as will best meet the local situation, with due regard to the needs of the patient, the community, the hospital and the physician.

It is the opinion of the committee that acceptance and practice of these principles will clarify the confusion that now exists regarding responsibility for the payment of medical hospital services and nonmedical hospital services, as defined above, by prepayment and other insurance plans.

In conclusion, the chairman wishes to record the fact that during the period of its intensive labors, holding prolonged meetings under adverse weather conditions, the committee averaged 90 per cent attendance. He wishes also to express the appreciation of the committee to those consulting advisers and others who have given so freely of their time: the president of the Society, Dr. Edward P. Bagg and the president-elect, Dr. Daniel B. Reardon, Drs. Allan M. Butler and Vlado A. Getting, of the Committee on Medical Economics, Dr. John F. Conlin, director of medical information and education of the Massachusetts Medical Society, and Dr. Nathaniel W. Faxon, substituting for Dr. Charles F. Wilinski, at the final meeting.

CASE 33491

PRESENTATION OF CASE

A seventy-one-year-old night watchman entered the hospital complaining of pain in the epigastrium and chest.

He had always been in good health until six weeks before entry, when he began to have epigastric distress, which he described as a vague soreness or feeling of pressure. This was not related to meals or other activities. During the following few weeks his appetite fell off, and he grew progressively weaker. The epigastric distress became more marked and more like pain in quality. This pain did not radiate. Two weeks before admission rather severe pain developed in the lower portion of the chest on both sides, which was definitely aggravated by coughing and deep breathing and relieved somewhat by lying on the right side. The pain often radiated to the left shoulder and axilla but was also felt at times in the right axilla. The patient denied fever or chills. There had been no nausea, vomiting or evidence of blood in the stools. The bowels moved normally until the week prior to admission, when the food intake decreased markedly. He had lost 15 pounds in weight during this illness.

Physical examination revealed a well developed, slim man who appeared chronically ill. He complained of an inconstant pain in the left shoulder and epigastric soreness. There was obvious distress on cough and inspiration. The chest showed poor expansion and was somewhat increased in the antero-posterior diameter. There was slight dullness in the left upper portion of the chest, and the breath sounds in the lower left portion were decreased. The diaphragmatic descent on both sides was poor. The heart was of normal size, with regular rhythm and no murmurs. There was slight distention of the abdomen, with tenderness and spasm in the epigastrium. High in the epigastrium, 5 cm. below the xiphoid process, an ill defined, hard, tender mass was palpable. This seemed to pulsate, and over it a soft to-and-fro souffle was heard. Liver dullness extended about 2 cm. below the costal margin. The

prostate was diffusely enlarged to about twice the normal size.

The temperature was 100.6°F, the pulse 66, and the respirations 28. The blood pressure was 125 systolic, 50 diastolic.

X-ray studies showed no abnormality of the esophagus, stomach or duodenum. There were a few diverticula in the sigmoid. No abnormal soft-tissue masses or calcifications were noted in the abdomen. Pyelograms disclosed good excretion of dye by both kidneys, without deformity of the calyces. A chest film revealed a small amount of fluid in the right pleural sinus and an area of increased density within the lung in the left pleural sinus. The heart was normal in size and shape. The aorta was not unusual. No shadow representing the gall bladder was demonstrated by Graham test.

Examination of the blood revealed a red-cell count of 2,750,000, with a hemoglobin of 9 gm., and a white-cell count of 7800, with 72 per cent neutrophils. Urinalysis demonstrated a specific gravity of 1.017, a + test for albumin and no sugar. The nonprotein nitrogen was 48 mg. per 100 cc., the total protein 6.13 gm., the albumin 3.94 gm., the globulin 2.19 gm., the calcium 8.8 mg., and the phosphorus 3 mg. per 100 cc., the serum amylase was 63 units, and the phosphatase 3 units. The van den Bergh reaction was 0.2 mg. per 100 cc. direct and 0.4 mg. indirect. The prothrombin time was 22 seconds (normal, 19 to 20 seconds). Three stools were guaiac negative.

During the patient's stay on the ward his condition remained unchanged for the first ten days. He continued to complain of epigastric pain. To some observers the epigastric mass seemed to have increased slightly in size during that period. In addition redness and tenderness were noted along the course of the left superficial saphenous vein. A review of the chest films showed multiple areas of increased density, some of which were linear in both lung fields.

On the twelfth hospital day the patient complained of severe pain under the left costal margin, which radiated up the side of the chest. Coughing and deep inspiration caused severe pain in this area. Later that day he became extremely weak and cyanotic and vomited 200 cc. of normal-appearing gastric contents. This was followed by unconsciousness and two generalized convulsions. He regained consciousness for a brief period, but a short time later gradually became comatose and expired.

DIFFERENTIAL DIAGNOSIS

DR. F. DENNETTE ADAMS: We have two distinct types of pain to explain: soreness or distress in the epigastrium soon developing into pain and, a month later, what appears to have been a new or different episode, located in the chest and aggravated by breathing and coughing. Although they may have originated from the same source, I believe that they

did not, it therefore seems wise to consider them separately

Occurring in a seventy-one-year-old man, the epigastric pain coupled with loss of appetite, increasing weakness and, what is very important, rapid loss of weight is most suggestive of malignant neoplasm. Quite properly, one first suspects the stomach. But considerable doubt is cast on this suspicion by the rapidity with which the illness developed and the absence of pain-to-food relation. Often in gastric carcinoma, because of ulceration, partial obstruction or interference with normal motility, pain is increased or decreased by eating. Failure of the roentgenologist to demonstrate a lesion also directs attention away from the stomach, although it by no means excludes disease in this organ.

DR WALTER BAUER May I interrupt at this point to say that this pain was rather constant?

DR ADAMS Did it go into the back?

DR BAUER I do not remember, I think not. But the constancy of the pain should be borne in mind. It was not related to meals. It was present all day and whenever the patient awakened at night.

DR ADAMS The easily palpable mass in the epigastrium points to a malignant tumor. But the picture is confused by the added facts that the mass pulsated and that, over it, a souffle could be heard. A highly vascular tumor might produce a souffle, I doubt if it would pulsate. These two signs taken into consideration with the character of the pain, emphasized by Dr. Bauer, demand consideration of abdominal aneurysm. In my opinion, however, the other symptoms, notably rapid loss of appetite, weight and strength, exclude this diagnosis. The pulsation and souffle must be discounted — one can explain them on the basis of transmission from the aorta as a result, perhaps, of pressure on the vessel by the mass itself.

The laboratory findings are not especially helpful. The anemia, with the history and stool examinations tending to exclude alimentary-tract bleeding, is consistent with cancer. The slight elevation of blood nonprotein nitrogen could have been caused by recent starvation and dehydration. The slightly increased serum amylase (54 to 55 units is to be regarded as top normal) may or may not have been significant. At least, it is not inconsistent with the diagnosis I propose to make.

I cannot get away from the speed with which the illness developed. The pain in the epigastrium and the rapid loss of weight and strength must have been due to a malignant lesion. The disease most likely to cause them in so short a period is cancer of the pancreas. I know of no other that, once it takes hold, will pull a patient downhill more quickly. The mass, the elevation of serum amylase and the negative gastrointestinal x-ray examinations can be regarded as important supplementary or confirmatory signs, as can the disturbance that I will

discuss in connection with the pain in the chest. Lymphoma should always be mentioned. This man could have had a lymphoma, but there are no special hints in the picture. The mass conceivably could have been the gall bladder, but I doubt it. We have no filling on the dye test. Perhaps autopsy will show a few small stones or a chronically diseased gall bladder, but if so, these findings will be incidental. The gall bladder could have been normal. Certainly, the primary cause of the illness was not in that organ.

We must now turn to a consideration of the pain in the chest — thus far disregarded but by no means forgotten repeated attacks first on both sides then on one or the other, often with extension into the shoulders or axillas and with aggravation by deep breathing. In a chronically ill person of this age, such attacks are almost certainly due to pulmonary embolism, irrespective of what can be seen by x-ray study. Even if the physical and roentgenologic examinations of the lungs were entirely negative, or if I were forced to make a diagnosis without benefit of x-ray film, I would come out flat-footedly with one of pulmonary embolism. Another important bit of evidence should be mentioned, it tends to confirm both primary and secondary diagnoses. It is well established that carcinoma favors the development of thrombophlebitis, and of the various carcinomas, that of the pancreas is the one most likely to do so. We have evidence of thrombophlebitis of one saphenous vein, even if no such signs could be demonstrated, I would still make the diagnosis.

May we see the x-ray films?

DR TOUFIC H. KALIL In the chest films an area of increased density is apparent in the region corresponding to the base of the left lower lobe, and the fluoroscopist seemed to think that this lesion was in the lung itself. These are linear areas of increased density that extend from the hilar region to the right lower lobe and the left lower lobe behind the heart, consistent with old, healed infarcts on the right and on the other side consistent with fresh infarction. So far as the abdominal condition is concerned, I do not see any outline of a soft-tissue mass except in the lateral film of the stomach. There may be some pressure on the posterior wall. Ordinarily, with carcinomas of the pancreas, particularly those in the head of the pancreas, there is widening of the duodenal loop. I do not see any in these films.

DR ADAMS With carcinoma of the head of the pancreas, we would also expect to find jaundice. If my reasoning is correct, the lesion will be found in the body of the pancreas.

The terminal episode seems typical of a large pulmonary embolism — another severe pain in the side, again with extension upward and aggravated by breathing and coughing, was undoubtedly pleuritic and probably diaphragmatic, later, cyanosis and unconsciousness occurred, followed by death. The

cyanosis is typical of a large pulmonary embolism, the spells of unconsciousness one can explain on the basis of temporary cerebral anoxia due to the circulatory insults. If death had been due to rupture of an abdominal aneurysm, abdominal or back pain or both would have been intensely severe, the picture of shock would have developed, cyanosis would not be striking, and the very last episode would have been longer — probably half an hour to a few hours.

Perhaps I am vulnerable in discounting the pulsation and the soufflé related to the mass and the failure of the gall bladder to fill with dye, but the other features of the case are so convincing that they force me to the diagnoses of carcinoma of the body of the pancreas, multiple thrombophlebitis, and multiple pulmonary embolism and infarction.

Dr. TRACY B. MALLORY: Dr. Bauer, will you tell us your impression?

Dr. BAUER: I thought that the patient had carcinoma of the pancreas. I must admit that when I first examined him I did feel this pulsating mass. From the time it was noticed the question was raised repeatedly whether or not we were dealing with an aortic aneurysm. Dr. Levine, who made the ward visit with me one day, favored that diagnosis. I thought that the nature of the pain itself was much more in favor of cancer of the pancreas, and I adhered to that. I was in error in the beginning when I interpreted the chest pain as part and parcel of one disease. Subsequent events left no doubt that the cause of death was pulmonary embolism.

Dr. FRANCIS D. MOORE: Is it not worth while observing that carcinoma behind the head of the pancreas can coexist with a palpable mass and not produce jaundice, a space-occupying lesion away from the ducts? Is it not notoriously a silent disease? Here was a man with pain that was bothering him a great deal, — rather sharp pain, — and as I listened to the story it sounded more like a vascular pain than a retroperitoneal pain.

Dr. BAUER: I did not think so as I saw him. In fact, this mass was not so impressive as might be gathered from the record. I thought that a slight compression of the abdominal aorta was responsible for the bruit that was heard.

Dr. ADAMS: I reasoned the way you did, Dr. Moore — but came up with a different conclusion: the tumor had been growing, silently perhaps, for a long time, but once it announced its presence, rapid decline of the patient occurred. This is my conception of the pattern usually followed by carcinoma of the pancreas. I do not see why a patient with aneurysm should go downhill so rapidly.

Dr. MOORE: Why not? He could have had a palpable, pulsating mass that came apart as it dissected along in new areas.

Dr. ADAMS: Possibly. But the 3 cases of abdominal aneurysms that I can recall at the moment have not shown constitutional manifestations such as

those that were predominant in this case. The patient had pain, — in front or in back, — but that is all until serious rupture occurred.

Dr. BAUER: It is a peculiar story for dissecting aneurysm. It was not intermittent pain. So far as I could ascertain the pain was present constantly twenty-four hours around the clock with no history of an initial episode of severe pain with associated shock followed by a period of relative freedom and then recurrence. It was not that type of story.

Dr. BENJAMIN CASTLEMAN: Pulsation is not observed with dissecting aneurysm, it occurs only with a saccular aneurysm.

Dr. BAUER: The question was whether or not it had dissected.

CLINICAL DIAGNOSES

Carcinoma of pancreas
Pulmonary infarcts, multiple.

Dr. ADAMS'S DIAGNOSES

Carcinoma of pancreas
Multiple thrombophlebitis
Multiple pulmonary embolism and infarction

ANATOMICAL DIAGNOSES

Carcinoma of body of pancreas
Thrombophlebitis of leg veins
Pulmonary embolism and infarctions, multiple
Diaphragmatic pleuritis
Arteriosclerosis, generalized
Cardiac hypertrophy, slight.

PATHOLOGICAL DISCUSSION

Dr. MALLORY: At post-mortem examination we found a large tumor mass arising from the body of the pancreas. The head and tail were free. The tumor had metastasized rather extensively to the regional lymph nodes, especially the retroperitoneal nodes, and a number of large nodes were found almost completely surrounding the aorta, which may have been compressed to some degree. There were scattered metastases in the liver as well.

The major pulmonary arteries showed no embolus, but when the small arteries in the lung were dissected, emboli were found in nearly every branch in both lower lobes and in the right middle lobe. These had resulted in infarction, whereas in the upper lobes emboli were also present but had not caused changes in the lungs. It is therefore likely that the terminal episode was the final embolic occlusion of the last patent arteries in the two upper lobes. The entire diaphragmatic pleura of both lower lobes and the superior surface of the diaphragm were covered with thick, fibrinous exudate about 2 mm thick. There is always some degree of pleuritis associated with pulmonary infarction, but it is relatively unusual to see such a thick, dense exudate as was present in this case.

The other findings were essentially incidental. There was severe arteriosclerosis of the abdominal aorta but no aneurysm or dilatation. There was a moderate grade of vascular nephritis, as well as a slight degree of cardiac hypertrophy, but nothing else of significance.

DR ADAMS: What about the gall bladder and bile ducts?

DR MALLORY: They contained no stones.

DR ADAMS: Did the patient have thrombosis throughout the vein, which I rather associate with cancer of the pancreas?

DR MALLORY: He had extensive thrombosis of the saphenous system and the deep veins in the calves of both legs.

DR MADELAINE BROWN: Was the brain examined?

DR MALLORY: No.

DR ADAMS: Three features of this case, in my opinion, cannot be emphasized too often. The first is the normal gall bladder, failure of the gall bladder to fill with dye does not always indicate gall-bladder disease — a fact frequently disregarded by clinicians and roentgenologists. The second consideration is the minimal signs of extensive thrombophlebitis, and the third the paucity of physical and x-ray signs in the lungs in the presence of extensive embolic disease. The diagnosis of embolic disease of the lungs must be made on the basis of history, backed by a knowledge of when and why it is likely to occur.

CASE 33492

PRESENTATION OF CASE

A sixty-nine-year-old jeweler was admitted to the hospital complaining of paralysis of the legs.

Six months prior to admission he began to experience pain high in the back, radiating around to the axillas and pectoral regions and severer on the left. Two weeks before entry he began to have numbness of the feet that had gradually extended upward to the legs and abdomen and, several days before entry, weakness, which rapidly progressed to paralysis of the legs. For the past two days he had experienced difficulty in voiding. There had been no headaches, vomiting, speech difficulty, dizziness or abnormal smell or taste. There was no history of convulsions or loss of consciousness.

There was a history of syphilis forty years before admission.

On physical examination the bladder was palpable several centimeters above the symphysis. There was complete paralysis of both legs. The arm jerks were normal, the abdominal reflexes were absent. The knee jerks were active, and the ankle jerk was absent on the right and weak on the left. The plantar reflexes were extensor. Pain and temperature sensibility were reduced below the third rib. Touch stimuli of medium intensity were felt on the chest and abdomen but not on the legs, and

vibratory sensation was lost below the lower sternum. There was a nontender kyphus or prominence of the upper thoracic spine. The right lobe of the prostate contained a firm, slightly irregular mass.

The blood pressure was 128 systolic, 82 diastolic.

Examination of the blood revealed a hemoglobin of 16 gm and a white-cell count of 21,600. The specific gravity of the urine was 1.010, the sediment contained rare red and white cells. X-ray films of the chest showed a complete collapse of the third thoracic vertebra, with slight wedging of the body of the second. No definite soft-tissue mass was seen in this region. The collapse was apparently due to destruction of the body of the vertebra. Slight pleural thickening was seen at the base of the right lung, the aorta was sclerotic and tortuous, the heart was within normal limits.

On admission a spinal tap revealed an initial pressure of 0, with no response to jugular compression, 12 lymphocytes per cubic millimeter and a ++ Pandy reaction. Pantopaque introduced at the third lumbar vertebra was arrested opposite the lower margin of the third rib. No cap was observed.

An operation was performed on the day of admission.

DIFFERENTIAL DIAGNOSIS

DR AUGUSTUS ROSE: May we see the x-ray films?

DR TOUFIC H. KALIL: The involved vertebra is entirely collapsed and disintegrated. On each side there is a fairly good joint space remaining. Immediately in front of the involved vertebra there is a little soft-tissue swelling.

DR ROSE: Do you see any other evidence of bone involvement?

DR KALIL: No, I do not. The second thoracic vertebra looks fairly good.

DR ROSE: What about the lung fields? Would you say that they are sufficiently clear to rule out x-ray evidence of metastatic disease?

DR KALIL: Yes, they are.

DR ROSE: What about the thickening of the pleura? Is that significant?

DR KALIL: Merely of old disease, especially at the right base and right apex, with a few linear areas of density extending into both apices.

DR ROSE: There is no active disease, but some soft-tissue swelling around the vertebrae, and I suppose you will agree that it is a bone destruction of the body of the vertebra.

DR KALIL: It seems so, unless it is an old fracture that has finally become decalcified, which might possibly give the same appearance.

DR ROSE: This was a sixty-nine-year-old man who had had pain in the upper portion of the chest for six months. Two weeks prior to admission, he developed a transverse myelitis. Evidence, particularly that of a spinal puncture, demonstrated that the myelitis was probably due to compression. The patient was promptly operated on. Generally, a

patient with compression myelitis should be operated on as quickly as possible, irrespective of the diagnosis. It has been variously estimated that if spinal cord is mechanically compressed for longer than six to eight hours, recovery is unlikely. Compression produces ischemia. Accordingly, in this patient operation was indicated as an emergency procedure — even though the surgeon very probably had fewer data for diagnosis than we have.

Before considering the various possibilities let us think of the myelitis. The myelitis was not complete. Touch was still felt on the chest and abdomen, although it was not felt on the lower extremities. Some impulses were passing through the compressed area of the spinal cord. The history of pain before the development of paralysis points to irritation of nerve roots, at the level of the third thoracic segment, as in a case of fractured vertebra or pressure from extramedullary tumor. Furthermore, the ascending paralysis with sensory loss is characteristic of an increasing compression of the spinal cord. Complete flaccid paralysis is consistent with compression of the cord, even though the plantar reflexes are extensor. The sensory level points to the level of the lesion. Loss of pinprick or temperature sensation is much more usual from any type of spinal-cord disorder than loss of touch sensation. The tendon reflexes in this case were different from what is expected in a rapidly developing transverse lesion of the upper thoracic cord. With Babinski signs, very active tendon reflexes are usually found. The absence of one ankle jerk and the reduction of the other raise the question of some other neurologic condition, possibly antedating the cord compression. Since we have the history of syphilis we ought to take that into consideration.

We then come to the differential diagnosis of the etiology of the compression. From the destruction of the body of the third thoracic vertebra, the kyphosis, the sensory level and the other neurologic findings, we must assume that the spinal-cord disease was at the level of the third thoracic vertebra. The Pantopaque examination showed no cap formation, the contrast medium was arrested at that level.

What conditions cause destruction of the body of the vertebra and secondary spinal-cord pressure? The first, of course is Pott's disease, or tuberculosis of the vertebra, of which there is no evidence in this case. Primary tumor of bone should come next in consideration but would have caused some distinctive features visible in the x-ray film.

Metastatic disease and syphilis are next in importance. Taking syphilis first, I believe that the history forty years previously may be significant. We are not told about the pupils.

Dr. CHARLES S. KUBIK: I believe that they were normal.

Dr. ROSE: The absence of one ankle jerk and the sluggish character of the other, in the presence of transverse myelitis, might be taken as evidence that

the patient had at least had neurosyphilis. Normal pupils make this less likely. Even if he had had neurosyphilis, other factors are necessary to explain the present illness. He could have had a gumma of the vertebral body, but again the gummatous lesions of the vertebra have distinctive features on x-ray study and are not usually confined to the body of one vertebra. Could the lesion have been a Charcot joint, with a compression fracture? Again, there would have been definite x-ray evidence, with bone proliferation and involvement of at least two vertebrae. Charcot joints of the spine are more often found in the lumbar, weight-bearing joints than in the upper thoracic portion of the spine. Before syphilis is discarded, one must mention gummatous involvement of the spinal dura, which is uncommon but is found in the lower cervical region and may give signs and symptoms of spinal-cord and nerve-root compression.

The rectal examination detected a nodular, slightly irregular firm mass in the prostate. Prostatic carcinoma is prone to metastasize to bone, especially the vertebrae. It is therefore possible, and I put as my first diagnosis a vertebral metastasis. The spinal-cord compression was secondary to a pathologic fracture of the diseased vertebra. I do not believe that syphilis played an important role in the present illness.

A PHYSICIAN: Is there any interpretation of the soft-tissue tumor lying opposite the lesion of the eighth to twelfth thoracic vertebrae?

Dr. ROSE: I believe that that is the descending aorta, which is tortuous.

CLINICAL DIAGNOSIS

Extradural upper thoracic spinal tumor

Dr. ROSE's DIAGNOSIS

Carcinoma of prostate, with metastasis to spine

ANATOMICAL DIAGNOSIS

Carcinoma of prostate, with metastasis to spine

PATHOLOGICAL DISCUSSION

Dr. WILLIAM SWEET: This man was operated on under local anesthesia because he had almost complete paralysis of the intercostal muscles. The fluid in the bronchi and lungs could not be raised when he attempted to cough. A laminectomy was carried out on the upper three thoracic vertebrae and disclosed reddish tissue suggesting neoplasm not only posterior to the dura but also on both sides and anterior to it. Before the lateral and anterior portions of the neoplasm were attacked the pedicles were removed to permit dissection in a direction always away from the dura and the spinal cord. It adds further stress to the operation in these cases to remove the pedicles, but I have been doing this because my results following laminectomy only have

been uniformly poor in patients with extradural malignant neoplasm who have developed a transverse lesion of the thoracic portion of the spinal cord. In this case a considerable mass of tissue suggesting neoplasm was encountered on the right side of the dura at the level of the second and third thoracic vertebrae. The bone of the vertebral bodies anteriorly was also grossly abnormal, and the prognosis for recovery of power in the legs was consequently poor. The postoperative course has thus far borne this out. The patient has recovered appreciation of touch, pinprick and temperature in the lower extremities, but there has been no suggestion of recovery of motor power.

DR KUBIK. I saw the patient when he was admitted. It seemed quite certain, even without a myelogram, that there was compression of the spinal cord. The level was fairly definite, and metastatic carcinoma seemed the most likely possibility. I thought, as Dr. Rose did, that whatever the lesion might be, immediate decompression of the cord was indicated.

This was a carcinoma of the prostate, with metastasis to the spine, which was responsible for the paralysis. As Dr. Sweet has pointed out, our experience here has been that when paralysis is as severe as it was in this case the prognosis is very nearly hopeless, particularly when the paralysis

develops suddenly or very rapidly. It is important to point out that this patient had pain in the chest and back, with radiation anteriorly, for a number of months before he developed any other neurologic symptom. It is more than likely that a diagnosis could have been made much earlier and compression of the spinal cord prevented. In 1942 we had a patient here with carcinoma of the prostate and metastasis to the lumbar spine, as well as with marked weakness of the legs, complete spinal subarachnoid block, xanthochromic fluid and a high protein below the block. Under treatment with stilbestrol the compression of the cauda equina was relieved, the paralysis cleared up, and the patient returned to work. He was all right four years later. We have heard that he was recently admitted to another hospital, presumably because of a recurrence of the metastases.

DR ROSE. Do you suppose that stilbestrol at the time of the last admission would have been of any value, in the presence of collapsed vertebrae and compression on a mechanical basis?

DR KUBIK. I think that the outlook is thoroughly poor but that the treatment should be tried. There was, as you pointed out, some sensation at the time of operation, indicating that transection of the spinal cord was not quite complete.

INFLUENZA

Most of the epidemics of influenza that have occurred in New England during the past few years have had their peak of incidence during the months of December and January. Those in which studies have been made here, as elsewhere, have been proved to be due to influenza virus—either influenza A or B. Vaccines containing strains of these viruses are now available commercially and have been used to a certain extent in the last three or four years in attempts to prevent the disease. At this time, therefore, many physicians and other interested individuals and groups are naturally raising the question of the value of such vaccines and whether or not they should be employed.

A comprehensive and critical review of the present status of the influenza problem is contained in this issue of the *Journal*. A report of the Study Com-

mittee on Vaccination Against Influenza of the American Public Health Association has also been published recently¹ and at least two preliminary reports on the experiences with vaccination against influenza in 1947 are also available.^{2,3}

One of the important epidemiologic features that has recently been stressed concerning influenza is the apparent periodicity of epidemics of this disease.⁴ This theory seems to permit the prediction within certain limits that an influenza epidemic will occur in any given year, as well as the type of influenza virus that is likely to be responsible for that epidemic. On the basis of a two-year to three-year cycle for influenza A epidemics and a four-year to six-year cycle for influenza B, an epidemic of the latter type was expected and materialized during the winter of 1945-46. There were at least 2 chances out of 3 that influenza A would occur during the same year and if it did not occur during that year, it was almost certain to occur the following winter.

Two events have transpired that, although they do not necessarily upset the fundamental theory, were somewhat disconcerting. In the first place, cases of influenza A were identified in several widely scattered areas either at the time of the influenza B epidemic or shortly thereafter.^{5,6} Secondly, an epidemic occurring in many parts of this country during the winter and early spring of 1947 was due to influenza A.^{7,8} It is by no means clear that these two outbreaks of influenza A in successive years were sufficiently widespread to be of significance in relation to the basic cycles of the influenza epidemics in this country. The most recent of these outbreaks, however, was disturbing in addition because of the fact that no definite protection was afforded to groups of persons who had been given vaccines containing influenza A and B during the months preceding that outbreak. This failure was in sharp contrast to the fairly good results obtained from vaccination during the influenza A epidemic of 1943-44 and the still better effects reported from immunization with A and B vaccine during the influenza B epidemic of 1945.^{9,10} The failures in 1947 proved to be due to a marked antigenic difference between strains of influenza A responsible for the 1947 epidemic when compared with the strains that had caused previous outbreaks.

Two of the strains from the earlier outbreaks had been incorporated in most of the vaccines that were available at the time

From these experiences it seems that the problem of influenza vaccination at the present time is by no means entirely solved. It also appears that unless the recent occurrences of influenza A were spurious or sharply limited, no widespread epidemic of either influenza A or B is to be anticipated in this country during the present winter. However, as pointed out in Dingle's review, further observations are necessary to test the validity of the theory of the periodicity of influenza, particularly in view of the antigenic differences among influenza viruses of the same type. Additional large-scale studies of the efficacy of influenza vaccination are also needed both in view of these differences and because of other factors concerned with the protective value of various types of vaccines.

"AN ADVENTURE IN CO-OPERATION"

THE sixth annual New England Postgraduate Assembly, held on the last three days of October, 1947, at the Copley Plaza Hotel in Boston and sponsored by the medical societies of the six New England States, broke all previous records for attendance. Over 700 physicians from Eastport, Maine, to Stamford, Connecticut, were registered, in addition to one each from California, Illinois and New Jersey, eight from New York and six from Canada. The program, previously announced to the medical profession of this section through the medium of these pages, was well selected and varied, the speakers, coming from major medical centers of the country, delivered their addresses ably and were appreciatively welcomed.

The dinner speaker on October 30, Dr. George Baehr, president of the New York Academy of

Medicine, presented his views on the continuing education of physicians to an audience of nearly one hundred and fifty. Dr. Baehr emphasized the changes that thirty years of scientific discovery have made in the training of the physician, dwelling particularly on the point that success in private practice can no longer be accepted as the criterion for a teacher. The quickened step of time in its march must be matched with new standards on our part—full-time clinical hospital chiefs, improvements in rural hospitals and a greater awareness of the responsibilities they owe to their communities, private-practice groups designed to fit in with the facilities of the community hospital and plans for prepaid medical care that are just rather than compulsory.

The real contribution of the Assembly, however, was the assurance it gave of success in the co-operative venture upon which the state medical societies of New England have embarked. Many of our problems are similar, and we can bring our varied experiences with them to bear on their solution. Others are unique for the background against which they are viewed, whether of rural Vermont or of industrial Rhode Island, and we can enrich our own knowledge by a little intermingling of it with that of our neighbors.

This desire for mutual improvement without other than healthy competition reflects the best of our sectional heritage and our pride in the particular homeland that we inhabit. Even as we take counsel with ourselves, however, to better our opportunities and improve our professional output, we are conscious of no antagonism to other sections of the country less fortunate than New England. Rather are we willing to share our benefits, to accept a moral and intellectual leadership, if necessary, to leaven the whole loaf.

MASSACHUSETTS MEDICAL SOCIETY BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

AVEDISYAN—Avedis D. Avedisyan, M.D., of Boston, died on November 16. He was in his seventy-fifth year.

Dr. Avedisyan received his degree from Tufts College Medical School in 1896.

His widow and a sister survive.

BEAN—Charles F. A. Bean, M.D., of Medford, died on July 23. He was in his sixty-third year.

Dr. Bean received his degree from Harvard Medical School in 1912. He was formerly house officer of the Malden Hospital and was later a member of the surgical staff of the Lawrence Memorial Hospital, Medford, as well as a censor and counselor of the Massachusetts Medical Society. He was a fellow of the American Medical Association.

His widow survives.

DELANO—Samuel Delano, M.D., of New Britain, Connecticut, died on November 8. He was in his ninety-eighth year.

Dr. Delano received his degree from Harvard Medical School in 1883.

HENDERSON—Francis F. Henderson, M.D., of Milton, died on November 20. He was in his sixty-second year.

Dr. Henderson received his degree from Tufts College Medical School in 1911. He was surgeon-in-chief, Fourth Surgical Service, Boston City Hospital, and a fellow of the American Medical Association.

His widow, two brothers and a sister survive.

SIBLEY—Benjamin E. Sibley, M.D., of Brookline, died on November 19. He was in his seventy-fourth year.

Dr. Sibley received his degree from Harvard Medical School in 1905. He served for more than thirty years as chief medical officer for the Boston Elevated and Metropolitan Transit Authority and was formerly a member of the medical staff of the Liberty Mutual Insurance Company and Massachusetts Institute of Technology. He was a fellow of the American Medical Association.

His widow, two daughters, four grandchildren and a sister survive.

MEDICOLEGAL ABSTRACT

Hospitals—Whose servant is the intern? On the principle that a charitable institution should be just before it is generous, many states hold charitable hospitals liable for the negligent acts of their servants. No liability is imposed for negligent acts of such persons as physicians and technicians when the hospital has not been negligent in their selection or retention. Cases imposing liability have been those concerning employees such as elevator operators, ambulance drivers, ward attendants and ministerial and administrative workers. An interesting question arises concerning the exact status of an intern—a graduate physician, but usually employed by the hospital. A recent Tennessee case involved that problem.

A pay patient was admitted to a charitable hospital, where she underwent a serious abdominal operation at the hands of her own surgeon. Shortly after the operation the surgeon ordered the administration of a hypodermoclysis. This was administered by Dr. L., an intern in the employ of the hospital. In a suit to recover damages for the negligent administration of the hypodermoclysis the

plaintiff alleged and testified that the injection on the right leg was made without the application of any preparation to the skin and without the use of gauze between the flesh and the needle, that this injection caused much pain and that forty to forty-five minutes elapsed from the starting of the flow until the return of the intern, and that during that time the area around the needle raised up a little, that the intern then removed the needle and administered a hypodermoclysis to the left leg, which was later without undue pain or untoward results, and that the place on the right leg continued to be painful and on the following morning was swollen and discolored and had a blister about the size of a silver dollar. The patient continued to suffer from this condition up to the time of discharge from the hospital and subsequently underwent a local operation on the right leg, which continued to cause great pain and suffering. A medical witness testified that if the solution had been pure and the equipment free of contamination and if the technique of the intern had been proper there would not have been any injury.

On a motion for a rehearing on appeal the attorneys for the hospital vigorously urged that even if the administration had been negligent the hospital would not be liable for the negligence of the intern. They relied largely on the language of Judge Cardozo in the case of *Schloerhoff v. The Society of New York Hospitals* (105 N. E. 92) in which it was stated as follows:

The second ground of the exemption is the relation subsisting between a hospital and the physicians who serve it. It is said that this relation is not one of master and servant, but that the physician occupies the position, so to speak, of an independent contractor following a separate calling, liable of course, for his own wrongs to the patient whom he undertakes to serve, but involving the hospital in no liability if due care has been taken in his selection.

The Tennessee court accepted the fact that it was the duty of the intern to follow the orders of the attending physician but stated:

A patient at the hospital is entitled to the generally accepted services of a hospital including the services of the intern. The intern can make no charge for his services. The patient has no voice in the selection of the intern. There is no contract between them. If the attending physician ordered a hypodermoclysis to be administered to a patient it would be the duty of the intern to give it. It was a part of the services rendered by the hospital by virtue of the relation existing between it and the patient.

The court then cited with approval the holding of the Supreme Court of Florida:

There can be no question but that a hospital is as much liable under the doctrine of respondent superior for the negligence of an intern who is in no wise an independent contractor, but a mere employee, as it is for that of a nurse under like employment.

It also cited the language of the Supreme Court of Virginia:

The intern is not an independent contractor so far as the patient is concerned. The contract is with the hos-

pital for his service. His service is a part of the numerous duties prescribed by the hospital, and he is selected, employed, directed, supervised and paid by the hospital. In rendering such services they act on behalf of their employer.

Judge Ketchum in dissenting relied largely upon the right to control the conduct of the person doing the wrong. He approved the reasoning of the *Schloendorff* case, saying

The hospital did not undertake to treat the plaintiff, or to furnish her with doctors or nurses, but merely furnished the room she occupied and the usual facilities of the hospital for treatment by her own physician and nurses. Dr. L., the intern who administered the hypodermoclysis, was a graduate physician who had been highly recommended to the hospital as a man fully qualified by reason of his education and skill to perform the duties of an intern, and in administering the hypodermoclysis he was acting under the directions of the plaintiff's own physician and not of the hospital. The hospital gave him no instructions in connection with the administering of the hypodermoclysis, which was an operation requiring the technical skill of an expert physician or nurse, and although it employed him as an intern it had no right to control or direct him as to the manner in which the operation should be performed.

Probably, this recent Tennessee decision does not lay to rest the question "whose servant is the intern?" Nor does it touch upon the problem of the status of the resident, in many hospitals a more advanced stage of internship. Is the intern his own master and solely responsible for his own negligence? Is he the servant of the hospital? If so, then the hospital may be liable. Or is he the servant of a private physician in charge, if any? If so, the physician in charge may be liable. The answer may vary in different states. In Tennessee, as a matter of law, the intern is an employee of the hospital and not the servant of the attending physician, and therefore any suit against the physician for the negligent acts of the intern would be unsuccessful. However, it is conceivable that the practice of the particular hospital regarding the supervision, control and direction of the work of an intern may be decisive. In view of the many decisions exempting hospitals from liability for the negligent acts of qualified specialists on the staff of the hospital, such as x-ray and surgical technicians, another state may well hold that an intern is in the same class as any other physician. (*Sepaugh v The Methodist Hospital*, 202, S. W. [2d] 985, 1946.)

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

THE CHANGING CANCER DEATH RATE

During the twenty-one years of the Massachusetts Cancer Program there has been a yearly increase averaging 130 deaths. About 60 per cent of the increase has been among males and 40 per cent among females. However, when allowance for the aging

of the population was made the rise was limited to the males, and there has been a downward trend among females. Not all types of cancer have contributed to this downward trend, for some have shown upward trends and others have been trendless. The mortality rates for cancer of the stomach, buccal cavity, skin, uterus and liver have downward trends. Cancer of the breast, larynx (female), vulva, vagina, scrotum, bladder, esophagus, kidney (female) and rectum (female) showed no significant trend, whereas an upward trend obtained for all remaining organs. The most pronounced in the upward trend group was cancer of the respiratory organs.

The upward trend of individual sites among males was sufficient to give a total upward trend, among females, the downward trend of individual sites was great enough to make a total downward trend. The change in the trend noted in Massachusetts among females was followed a few years later by a similar drop in other states. The change in the adjusted cancer death rate offers speculation regarding the part that can be attributed to cancer-control activities and other circumstances.

HOMOLOGOUS SERUM JAUNDICE FOLLOWING BLOOD AND PLASMA TRANSFUSIONS

The risk of transmitting jaundice in plasma has been generally appreciated in this country since the outbreak of jaundice in the United States Army camps in 1942¹ was traced to plasma used in the preparation of yellow-fever vaccine. There have been numerous reports of this disease after blood and plasma transfusions in both Army and civilian practice.²⁻⁴ It has also been transmitted by unsterile syringes at venereal-disease clinics.⁵ More recent surveys in New York State⁶ and England⁷ showed attack rates of roughly 5 and 7 per cent, respectively. In Boston Scheinberg, Kinney and Janeway⁸ and Moloney⁹ have reported further civilian cases. These reports re-emphasize the necessity of weighing the immediate advantages of blood and plasma transfusion against a possible chance of a later attack of jaundice.

To facilitate follow-up studies, the State Biological Laboratory issues an information card with each unit of blood and plasma distributed. The prompt return of this card with details of the patient's name and address and lot number of plasma used make possible a check for immediate reactions, and is also the nucleus for a further follow-up study four to six months later. Such a study to ascertain the incidence of this disease in Massachusetts is now in progress under the auspices of the American Red Cross, the Harvard School of Public Health and the Massachusetts Department of Public Health.

Where cards have not already been sent in, hospitals are asked to assist the study with the relevant data

Undulant fever	3	3	3
Whooping cough	461	551	555

*Three-year median.

†Five-year median.

COMMENT

Diseases above the seven year median are bacillary dysentery, diphtheria, dog bite, German measles, mumps, poliomyelitis, salmonellosis, pulmonary tuberculosis and typhoid fever. However, in none of these is the rise sufficient to cause concern.

Diseases below the seven year median are chicken pox, gonorrhea, malaria, measles, meningococcal meningitis, lobar pneumonia, scarlet fever, syphilis, undulant fever and whooping cough.

With 66 cases of poliomyelitis being reported for October it seems evident that the peak was reached in September when 149 cases were reported.

Although diphtheria is much below the prevalence of October, 1946, it still exceeds the seven-year median. In fact only twice since 1935 has the October figure been so high. With the diphtheria season just beginning a further increase can be expected in communities where immunization is not at a high level.

After a low year in 1946 following the epidemic prevalence in 1945, mumps has maintained an upward trend in 1947. This probably indicates that the disease will be prevalent during the coming season, with the usual peak in March or April.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Boston, 9, Cambridge 1, Chelsea 5, Dudley, 1, Foxboro 1; Framingham, 1, Randolph, 1, Revere, 1, Somerville, 1 total 21

Dysentery bacillary was reported from Chelsea, 3, Malden 1, Waltham (Fernald State School), 2, Wellesley 1, Worcester (State Hospital) 7, Wrentham (State School), 46 total 60.

Hookworm was reported from Templeton 1, total 1. Lymphocytic choriomeningitis was reported from Athol 1, total 1.

Malaria was reported from Medford, 2, Woburn 1, Worcester, 1 total, 4.

Meningitis meningococcal, was reported from Boston, 2, Newton, 1; Quincy 1, Waltham, 1, Westfield, 1 total, 6.

Meningitis, Pfeiffer bacillus, was reported from Wellesley, 1, Worcester 1 total 2.

Meningitis pneumococcal was reported from Cambridge 1, Lawrence, 1, total, 2.

Meningitis undetermined was reported from Springfield, 1, Worcester, 1, total, 2.

Poliomyelitis was reported from Attleboro, 1, Boston 3, Cambridge, 3, Chelsea 1, Chicopee, 1, Concord 1, Dedham 1, Easton, 2, Everett, 1, Falmouth, 1, Fitchburg 2, Gloucester 1, Lawrence, 1, Leominster, 1, Lynn 7, Malden 1, Manchester, 1, Medford 1, Medford 2, Melrose, 1, Middleboro, 1, New Bedford 1, Newton 4, Quincy, 3, Revere, 2, Saugus 1, Springfield 2, Stoughton 1, Swansea 1, Taunton 1, Wakefield, 2, Waltham, 1, Watertown 1, Wellerley, 7, Williamsburg 1, Woburn 1, Worcester 3 total, 66.

Salmonellosis was reported from Ayer 1, Beverly 2, Boston, 2, Chelsea 3, Ipswich 1, Lowell 1, Marshfield 1, Melrose, 1, Winchester 1, Worcester, 1 total, 14.

Septic sore throat was reported from Boston, 1, Greenfield 1, Haverhill 2, Melrose 1 total, 5.

Tetanus was reported from Arlington 1, Boston 3, Lakeville, 1, Middleboro, 1, Plymouth 1 total, 7.

Tularemia was reported from Holyoke, 2 total 2.

Typhoid fever was reported from Chelsea, 1, Clinton, 4, Everett, 1, Orange, 1, Worcester 1 total, 8.

Undulant fever was reported from Brimfield, 1, Clinton, 1, Woburn 1 total, 3.

MISCELLANY

AMERICAN MEDICAL DIRECTORY

Cards are being sent to all physicians in the United States its dependencies and Canada requesting information to be used in compiling the new *American Medical Directory*. This eighteenth edition the first since 1942, has been long delayed on account of wartime restrictions and the shortage of paper and labor.

Its completeness and accuracy are obviously of vital importance. Any physician who had failed to receive a card by December 1 is urged to write at once to the Directory Department of the American Medical Association requesting a duplicate.

AWARD TO COLONEI MOORE

Colonel Merrill Moore, of Boston was awarded the Chinese decoration Yen Hui Special Class, on Saturday November 1, at a ceremony held at the quarters of Lieutenant General Albert C. Wedemeyer formerly commanding general, United States Forces China Theater at Fort George G. Meade, Maryland. The decoration was awarded in recognition of outstanding and meritorious service during 1946 while Colonel Moore was on duty as surgeon to the Nanking Headquarters Command General Peter Pi military aide to the Chinese Embassy in Washington and formerly aide to the Generalissimo. The presentation was made by General J. L. Huang of the Chinese Army, who was a classmate of Colonel Moore at Vanderbilt University. Colonel Moore had served with distinction in the South Pacific Theater in 1942-1944 and in the Philippines in 1945 prior to his assignment to the China Theater.

BOOK REVIEWS

Handbook of Correctional Psychology Edited by Robert M Lindner, M D, and Robert V Selger, M.D. 8°, cloth, 691 pp New York Philosophical Library, 1947 \$10 00

This book is a veritable safety deposit vault of valuable information. Forty-six experts have co-operated, under the editorial guidance of two able scientists, to bring together the most up-to-date and progressive opinions available concerning the application of psychology to the problem of correcting behavior difficulties. Anyone interested in good government will find this volume worth reading. Its point of view is very broad, but particular problems are given specific attention in the light of common knowledge shared by modern psychiatrists. This is a book that the psychiatrists or social workers will find informative and helpful.

The Development of Modern Medicine An interpretation of the social and scientific factors involved By Richard Harrison Shryock. 8°, cloth, 567 pp, with 9 plates New York Alfred A Knopf, 1947 \$5 00

The book, long out of print, was first issued in 1936. It now appears in an enlarged and revised form, brought up to date. The author, a competent general historian, is the leading lay authority on the form of modern medicine now practised in the United States. This thoughtful monograph was widely proclaimed when first published as the best summary of the historical development of medicine in print. The new edition is equally satisfactory. The author handles the more recent controversial matters, such as the programs for socialized practice, the stand taken by the American Medical Association and the pending bills for federal legislation of compulsory health insurance, with great clarity of thought, without aligning himself with any one of the proposals. A particularly well written chapter deals with psychiatry and the impact of Freud on the advance against mental disease. Fully annotated and with a good index, the finely printed volume is a credit to both author and publisher. It is an authoritative text, and the new impression is a welcome addition to the medical literature of our times.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Hospital Care in the United States A study of the function of the general hospital. Its role in the care of all types of illness, and the conduct of activities related to patient service, with recommendations for its extension and integration for more adequate care of the American public 8°, cloth, 631 pp, with 94 tables and 58 charts New York The Commonwealth Fund, 1947 \$4 50

Diseases of the Gallbladder and Allied Structures Diagnosis and treatment By Moses Behrend, M D, consulting surgeon, Jewish Hospital and Mt. Sinai Hospital, and associate in surgery, Jefferson Medical College. With a foreword by Thomas A Shallow, M D, Samuel D Gross, professor of Surgery, Jefferson Medical College. 8°, cloth, 290 pp, with 110 illustrations Philadelphia F A Davis Company, 1947 \$7 00

The Engrammes of Psychiatry By J M Nielsen, M D, associate clinical professor of neurology and psychiatry, University of Southern California School of Medicine, and senior attending physician (neurology), Los Angeles General Hospital, and George N Thompson, M D, assistant clinical professor of neurology and psychiatry, University of Southern California School of Medicine and psychiatric consultant, Department of Corrections, State of California. 8°, cloth, 509 pp, with 28 illustrations Springfield, Illinois Charles C Thomas, 1947 \$6 75

Neuropathology in its Clinicopathologic Aspects By I Mark Scheinker, M D, assistant professor of medicine (neurology) and instructor in neuropathology, University of Cincinnati College of Medicine, and neuropathologist and attending

neurologist, Cincinnati General Hospital. With a foreword by Tracy J Putnam, M D, professor of neurology and neurologic surgery, College of Physicians and Surgeons, Columbia University, and director of services of neurology and neurologic surgery, Neurological Institute of New York. 8°, cloth, 306 pp, with 208 illustrations Springfield, Illinois Charles C Thomas, 1947 \$6 75

NOTICES

ANNOUNCEMENTS

Dr Robert L Mason has returned from military service and is resuming the practice of surgery at 47 Bay State Road, Boston.

Dr Francis Rouillard announces the removal of his office for the practice of obstetrics and gynecology to 1180 Beacon Street, Brookline.

JOSEPH H PRATT
DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a m

MEDICAL CONFERENCE PROGRAM

Wednesday, December 10 — The Clinical Significance of Hyperlipemia Dr Robert Holden

Friday, December 12 — Exophthalmos and Proptosis Dr Parker Heath

Wednesday, December 17 — Clinicopathological Conference Drs James M Baty and H E MacMahon

Friday, December 19 — Gastritis Dr Seymour Gray

On Tuesday and Thursday mornings from 9:00 to 10:00 Dr S J Thannhauser will give medical clinics on hospital cases. On Friday afternoons from 2:00 to 4:00 therapeutic conferences will be held with round-table discussion, Dr R P McCombs, Moderator. On the second and fourth Friday afternoons of each month, Dr Merrill Sosman will conduct x-ray conferences from 4:00 to 6:00. On Saturday mornings from 9:00 to 10:00, clinics will be given by Dr William Dameshek. Medical rounds are conducted each weekday except Saturday by members of the Staff from 12:00 to 1:00.

All exercises are open to the medical profession. There will be no conferences from December 24, 1947, to January 3, 1948, inclusive.

TUFTS ALPHA OMEGA ALPHA

The Tufts chapter of the Alpha Omega Alpha will meet in the auditorium of the Beth Israel Hospital on Wednesday, December 10, at 8:30 p m. Dr Richard H Overholt will speak on the subject, "The Mechanics of Treatment in Pulmonary Tuberculosis."

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, December 16, at 8:15 p m. A symposium on recent advances in endocrinology will be presented.

PROGRAM

The Use of Thiouracil Derivatives in the Treatment of Thyrotoxicosis Dr Mark F Lesses

Radioactive Iodine in the Treatment of Thyrotoxicosis Dr Saul Hertz.

Adrenal Insufficiency Dr Kendall Emerson

Retarded Adolescence. Dr Nathan B Talbot.

HELEN PUTNAM FELLOWSHIP

The Helen Putnam Fellowship for advanced research in the field of genetics or of mental health will be offered by Radcliffe College for the academic year 1948-1949.

This fellowship, carrying a stipend of \$2000 for an eleven-month period and beginning October 1, 1948, is open to mature women scholars who have their doctorate or equivalent qualifications, and who have research in progress.

Applications should be submitted to Radcliffe College not later than April 1, 1948. The appointment will be announced on approximately May 1, 1948.

LATE EFFECTS OF TOTAL GASTRECTOMY IN MAN*

ROBERT M. MACDONALD, M.D.,† FRANZ J. INGELFINGER, M.D.,‡ AND HELEN W. BELDING, M.D.§

BOSTON

STUDIES on patients who have survived total gastrectomy for three years or more are few, and contradictory results are reported. For this reason and since total gastrectomy is being practiced with rapidly increasing frequency, we have studied intestinal motor function, intestinal absorption, pancreatic function and the blood picture in 3 patients who have survived total gastrectomy for three, five and ten years, respectively.¶

CASE REPORTS

CASE 1. E. O., a 58-year-old woman was admitted to the hospital with a history of anorexia, weight loss and vomiting of 3 years duration. A total gastrectomy with enterointerostomy was performed on May 28, 1936. The pathological diagnosis of Dr. Tracy B. Mallory was adenocarcinoma without metastases to the adjacent lymph nodes or extension to the duodenum. One year later when reoperation was necessary to establish a new enterointerostomy, no evidence of cancer was discovered. Since the second operation, the patient's condition has been excellent, and she has carried on her work as a housekeeper without difficulty. Postoperatively she received liver and iron prophylactically until July 15, 1946.

CASE 2. R. V., a 49-year-old Italian was admitted to the hospital with a history of increasing pallor, weakness and anorexia of indefinite duration. For 2 weeks he had felt a mass in the abdomen. On August 20, 1941 a total gastrectomy, splenectomy, subtotal pancreatectomy and enterointerostomy were performed. The pathological diagnosis of Dr. Mallory was adenocarcinoma. The patient made a moderately good recovery and slowly regained weight. Three years after operation the red-cell count was 4,400,000, with a hemoglobin of 80 per cent. At the end of 5 years, when he was first seen at this hospital, he had lost 10 pounds in weight although he was still feeling moderately well. Blood studies revealed macrocytosis and hyperchromia (Table 1).

CASE 3. W. M., a 41-year-old man was admitted to the hospital with a history of intermittent indigestion of 8 years and epigastric pain, poor appetite and weight loss of 4 months duration. X-ray examination revealed an ulcer high on the lesser curvature. Since cancer was suspected total gastrec-

tomy was carried out on August 8, 1943. The pathological diagnosis of Doctor Benjamin Castleman was acute and chronic gastritis with multiple gastric ulcers. The patient was discharged on the 13th postoperative day and remained well for 2 years. He then began to lose his appetite and to feel weak. Pallor was noted and examination of the blood showed a macrocytic, hyperchromic anemia, which responded to injections of liver extract (Table 1). No liver was given after July 9, 1946, but no anemia had developed as of March 17, 1947.

GASTROINTESTINAL FUNCTION

When the first patient who survived total gastrectomy was studied fifty years ago, it was noted with surprise that she regained her appetite,²²⁻²⁴ and since then, others have observed that the stomach is not necessary for this sensation.²⁷⁻³⁰ All our patients have a normal desire for food and develop hunger. The patient in Case 1 takes three meals a day and only occasionally eats between meals, the meals are of nearly normal size. Another patient (Case 2) has persisted in taking in-between feedings and a bedtime snack. The third patient has to eat irregularly because of his work, but four times a day, on the average, he takes meals about two thirds the size of those consumed before his illness. All 3 patients are on an unrestricted, mixed diet, but take care that the food is well cut and well chewed. Occasionally, they experience borborygmi and mild upper abdominal cramps after eating, and too rapid eating may produce an epigastric sensation of fullness. None of these patients have dysphagia or symptoms suggesting the "dumping syndrome." The weight, although it increased after the operation, has never regained the levels existing before illness.

Fluoroscopic and radiologic examination revealed a normal esophagus and a patent, well functioning esophagojejunal anastomosis. In Cases 1 and 2 the jejunal segment at the anastomosis was dilated, with no mucosal markings except a few thickened valvulae conniventes. The barium meal tended to puddle in these jejunal reservoirs (Fig. 1). In Case 3 jejunal dilatation was not seen. The motor pattern of the lower jejunum and ileum of all 3 patients mani-

§Assistant in medicine, Department of Medicine, Boston University School of Medicine; fellow in medicine, Robert Dawson Evans Memorial Hospital.

¶These cases were made available through the courtesy of Dr. Reginald H. Smithwick, who has described the operative details elsewhere.

||These observations were made by Dr. James A. Hilsted at the Mass General Hospital.

fested minimal to moderate abnormalities of the type seen in the "deficiency pattern" of Golden³¹ Films taken five hours after the ingestion of the barium meal demonstrated the opaque medium in the ileum and ascending colon in Case 1 In Case 3, however, the meal was still confined to the small bowel, and in Case 2 only a few jejunal loops were seen, most of the meal still being retained in the jejunal reservoir The twenty-four-hour films showed a normal distribution of the barium meal in all 3 cases

Kymographic records of small-intestine motility were obtained by a method previously described²²

tain chyme for considerable periods, are prone to develop after total gastrectomy, presumably in an attempt to compensate for the absent reservoir function of the stomach The findings in Case 3, however, suggest that this jejunal dilatation is neither invariable nor apparently necessary

Studies of fat absorption were carried out as follows The patients, who were on a routine hospital diet, ingested between 40 and 60 gm of fat a day An accurate and constant fat intake was not feasible because the subjects, who felt perfectly healthy, did not wish to stay in the hospital for more than a week, and many tests were carried out during that time.

TABLE 1 Blood Findings in Patients Who Lived Three or More Years after Total Gastrectomy

SURGEON	DATE OF OPERATION	AGE	SEX	DIAGNOSIS	ONSET OF ANEMIA AFTER OPERATION	RED CELL COUNT	HEMOGLOBIN	COLOR INDEX
Patients developing macrocytic blood picture								
Dennig ²	1918	41	M	Ulcer	yr 8	$\times 10^6$ 1.4	35%	1.25

Moynihan ²⁰	1907	43	M	Carcinoma	3	—	—	—
Streicher ^{21, 22}	1932	45	F	Carcinoma	3	—	—	—

The motility records corresponded well with the roentgenologic findings (Fig 2) The jejunum near the anastomosis in Cases 1 and 2 exhibited atony and an absent wave pattern. Only after motility had been stimulated by the ingestion of an egg-nog did motor waves appear The lower jejunum in Cases 1 and 2 and the entire jejunum in Case 3 yielded essentially normal motility records Both radiologic and motility studies of the intestine indicate that large jejunal reservoirs, which may re-

The stools were collected for three days, acidified and dried in toto over a steam bath The dried feces were then finely powdered, and a 10-gm portion was extracted in a Soxhlet apparatus with petroleum ether With such a method, some volatile lipids may be lost, but difficulties encountered with wet methods, such as small, nonrepresentative aliquots and difficult fat extraction, are avoided

When the intake of fat is small, the absolute daily fecal fat excretion is more significant than the pro-

portion of fat output to fat intake, or the percentage of fat in the dried stool.²² A normal person ingesting no more than 60 gm of fat a day usually excretes less than 5 gm and invariably less than 10 gm in the stools. According to these criteria, the fecal fat excretion of 2 patients was in the high normal range (Table 2), whereas only Case 2 exhibited a frankly abnormal output of fat in the stools. This patient, it will be recalled, had undergone a partial pancreatectomy.

Table 2 also lists the findings of others who have studied fat absorption after total gastrectomy.^{14, 25, 26, 31-33} The wide divergence of results is

data, which others have also found difficult to interpret.³¹ Nevertheless, even after exclusion of cases that are theoretically subject to criticism, one is confronted, on the one hand, by a patient who a year after operation lost 23 gm of fat²⁵ and, on the other, by a patient who four years after operation excreted less fat than many a normal person does.³⁷

Although an occasional case with frank steatorrhea may be encountered, the data presented in the literature and our own studies indicate that fat absorption is only mildly impaired in patients who have survived total gastrectomy for two or more years. If the fat intake is low, the absolute amount of fat

—	—	—	—	—	Blood smear showed macrocytosis and hyperchromasia; patient responded to liver and iron therapy and was living 8 yr postoperatively.
136	—	—	21.6	4.7	Blood smear showed nucleated red cells: spinal-cord changes observed; no response to intravenous folic acid, but patient responded to liver therapy and was living 8 yr postoperatively.
—	—	—	—	—	Patient had chronic diarrhea: patient died nearly 4 yr postoperatively.
—	—	8.1	—	—	Blood smear showed moderate macrocytosis, no megaloblastic changes in bone marrow; liver response not reported: patient living 9 yr postoperatively.
—	—	—	—	8.43	Reticulocyte count: 1.2 per cent; blood smear and bone marrow typical of pernicious anemia; no response to extrinsic factor and vitamin C; patient responded to liver therapy but died 6 yr postoperatively.
—	—	—	—	1.15	Patient, who responded to liver therapy, was living 20 yr postoperatively.
106	—	—	17.0	2.45	Patient, who responded to liver therapy, was living 6.5 yr postoperatively.
122	—	—	44.0	7.65	Patient, who responded to oral folic acid therapy, was living 5 yr postoperatively.
118	37.9	—	34.2	6.87	No bone-marrow biopsy: slight response to prolonged folic acid therapy; patient living 5.5 yr postoperatively.
—	—	—	—	5.0	Blood smear showed macrocytosis, anisocytosis and tailed cells, no bone marrow biopsy; patient, who responded to liver therapy, living 3.5 yr postoperatively.
115	40.9	—	14.7	2.2	Blood smear showed macrocytosis; bone marrow showed megaloblastic picture; patient, who responded to oral folic acid therapy, living 9 yr postoperatively.
—	—	—	—	4.2	Blood smear similar to that in pernicious anemia, but no nucleated red cells seen; 1 liver biopsy; patient probably that referred to by Daculsi ³⁸ as having died of pernicious anemia 11 yr postoperatively.
—	—	—	—	—	No response to liver until administration of iron intravenously; patient living 8 yr postoperatively.
—	—	—	—	—	Blood picture stated to reveal "macrocytic anemia"; patient responded to liver therapy but died of metastasis 3.5 yr postoperatively.
—	—	—	—	—	Blood picture stated to reveal "profound anemia" (no blood count given); patient improved but relapsed, dying 3.7 yr postoperatively; no metastasis found at autopsy (incomplete study).
—	—	—	—	—	Macrocytic anemia: stated to have developed while patient was on prophylactic liver therapy; patient died of metastasis 4 yr postoperatively.

striking but can partly be attributed to differences in fat intake and in subject material. In some cases, for example, the patients were studied early in the postoperative period before readjustment of gastrointestinal function was complete, in others, the patients subsequently died of recurrent carcinoma and the result that the effects of total gastrectomy and of the recurrent disease are hard to separate. The report of Heilmann,⁴¹ often credited with describing a fat loss of 52 to 74 per cent, contains equivocal

lost is not large, but on high-fat diets, a considerable excretion of fecal fat may take place. The careful studies of Wollaege et al⁴² indicate that fat absorption is similarly affected after partial gastrectomy.

The absorption of fat-like substances was further studied by means of the vitamin A tolerance test, 300,000 units being given by mouth. The results indicate that the blood in Cases 1 and 3 achieved a normal increase of vitamin A but that the tolerance curve in Case 2 was quite flat (Fig. 3). A remarkable

feature is the delayed absorption of the vitamin that appears to take place in all these cases. When vitamin A is injected into the jejunum of a normal person, the blood level is sharply elevated two hours after the injection.⁴⁶ The two-hour to three-hour levels of vitamin A in the gastrectomy cases, contrary to all expectations, were lower than corresponding levels obtained in normal persons taking the test dose by mouth. Two possible explanations are offered for the delayed absorption of vitamin A: the test dose, which is small in volume, is retained in the jejunal reservoirs until the patient is allowed

to eat and drink (after the three-hour sample), and pancreatic and biliary secretions, which facilitate the absorption of vitamin A⁴⁶ and which enter the bowel considerably above the esophagojejunal anastomosis, mix with the test dose only after considerable delay.

It has been postulated that the secretion of pancreatic enzymes is greatly reduced after removal of the stomach.⁴⁷ Deficient pancreatic secretion may result either because the vagi are sectioned at operation or because the duodenal mucosa does not elaborate secretin normally if acid chyme fails to enter the duodenum. Pancreatic-enzyme studies in our cases, however, yielded essentially normal figures

to eat and drink (after the three-hour sample), and pancreatic and biliary secretions, which facilitate the absorption of vitamin A⁴⁶ and which enter the bowel considerably above the esophagojejunal anastomosis, mix with the test dose only after considerable delay.

Judging from the prothrombin times (Table 3), the absorption of fat-soluble vitamin K is adequate. The normal serum levels of calcium and phosphorus also indicate that at least some vitamin D is being absorbed. Roentgenograms of the spine and pelvis revealed normal bone studies in 2 cases. In Case 1 considerable osteoporosis was noted, but no more than was evident before operation.

A normal person on an average diet excretes between 1 and 2 gm of nitrogen a day.⁴⁹ As Table 2 indicates, our cases and those reported in the litera-

ture show little variation from normal. The largest nitrogen loss, 4.8 gm, was reported by Bull,⁵¹ whose patient was studied three and a half months after operation and was given a high-fat diet.

Standard methods for collecting pancreatic secretions from the duodenum could not be carried out because of the operative procedure. Furthermore, it was considered desirable to determine the response of the pancreas to food intake after total gastrectomy rather than the response to Mecholyl or secretin. Accordingly, an egg-nog of standard composition was given to each patient after a collecting tube had been placed in the jejunum under fluoroscopic control. Half an hour later, constant suction was applied, and intestinal chyme collected in an iced container for one hour. The aspirated material was relatively free of egg-nog.

None of the patients had symptoms referable to biliary-tract disease. An oral Graham-Cole test in

Case 1 did not demonstrate any gall-bladder shadow. The other patients received the dye intravenously, and a normal filling of the viscus resulted in both

reasons absorption from the dilated small bowel is often subnormal, and dilatation of jejunal segments not only may delay fat absorption by the pooling

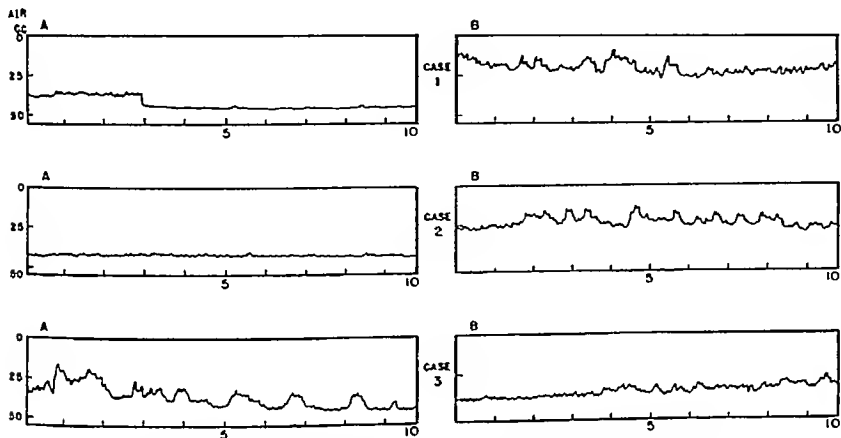

FIGURE 2. Balloon kymographic tracings of jejunal motility in Cases 1, 2, and 3.

Tracing A was taken just below the esophageal anastomosis; tracing B refers to the lower jejunum. The vertical calibrations refer to air in the balloon, and the horizontal markings to time in minutes.

cases, administration of a fat meal produced normal emptying of the gall bladder.

Glucose-tolerance curves obtained after the 3 subjects had ingested 50 gm of glucose in 200 cc of water are presented in Figure 4. The early hyperglycemia that occurs in patients with extensive gastrectomies because a large quantity of hypertonic glucose solution rapidly enters the small intestine is well demonstrated and apparently is not affected by the presence of jejunal reservoirs. After the initial rise in blood sugar, a hypoglycemia attributed to excessively stimulated glucose removal mechanisms has been found in some of these patients,^{17, 18} but such a response was not observed in our subjects. As a matter of fact, Case 2 exhibited a continuing hyperglycemia of the diabetic type, possibly related to the partial pancreatectomy that had been performed.

Significant impairment of fat absorption was demonstrated only in Case 2, but the deficiency of pancreatic enzymes in this patient suggests that the partial pancreatectomy was at least a contributing factor in the pathogenesis of the steatorrhea. In general, our studies indicated that such loss of fecal fat as may occur after total gastrectomy is not due to deranged function of the biliary tract or pancreas. By analogy to the delayed absorption of vitamin A, however, it is possible that the absorption of fats is impaired by mechanical disorders, for the following

of ingested food but also may decrease fat absorption by curtailing the length of normally functioning small intestine, and if jejunal pooling is minimal or

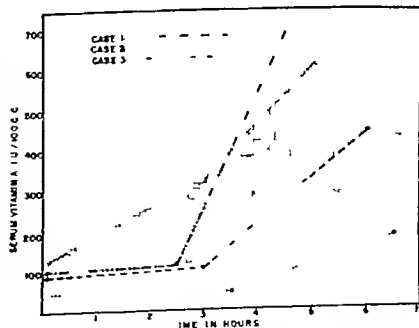

FIGURE 3. Vitamin A Tolerance Curves following Oral Ingestion of 500,000 International Units.

The shaded area represents the normal range.

is counteracted by the ingestion of a large meal, fats may be propelled for some distance down the intestine before pancreatic and biliary secretions

"catch up" with the meal. Under such conditions, fat absorption may be impaired because a relatively short stretch of small bowel is exposed to properly digested fats. In this connection, the pancreatic-function studies indicated that the jejunal reservoirs were practically free of egg-nog half an hour after its

hematologic findings in the other case were normal, but the patient had received liver prophylactically after operation. This incidence of macrocytic anemia prompted a renewed inquiry into the much debated question whether total gastrectomy predisposes toward a pernicious-anemia type of blood

ingestion, but that at that time considerable quantities of relatively pure bile and pancreatic juice had collected in the dilated bowel loops.

Speculation concerning the ultimate effects of vagotomy on biliary, pancreatic and intestinal function has recently been rife. Since complete vagotomy is almost always performed during total gastrectomy,

picture. On theoretical grounds, it should, for Castle^{54, 55} has shown that in man, as opposed to some animals,⁵⁶ the stomach is the only source of the intrinsic antianemic factor. Clinical experience, however, suggests that total gastrectomy in man is not followed by a macrocytic hyperchromic anemia, although an iron-deficiency anemia occasionally

it is of interest that our patients did not manifest the dire results that have been predicted as sequelae to section of the vagus nerves.

MACROCYTIC ANEMIA

As shown in Table 1, 2 patients developed a macrocytic, hyperchromic anemia two and five years, respectively, after total gastrectomy. The

occurs. Thus, Pack and McNeer⁵⁷ state that a macrocytic anemia is rare after total gastrectomy, and that when it is found, it is seldom hyperchromic and usually does not respond to adequate liver therapy.

The blood findings in our patients suggested the hypothesis, which had already been advanced by others,⁵⁸ that patients with total gastrectomy de-

velop macrocytosis and hyperchromia provided they live long enough after the operation. For this reason, we have collected from the literature and by personal correspondence as many cases of three-year survival after total gastrectomy as possible, and have attempted to ascertain the incidence of macrocytic anemia in this group 2-25, 27-30, 31, 33, 34-35. Some cases previously cited as three-year survivals

died one year postoperatively of acute small-bowel obstruction. At autopsy no evidence was found of recurrence of carcinoma. This case has been omitted from Table 1, which is limited to three-year survivals.

The 29 patients who apparently did not develop a macrocytic anemia include 10 who definitely had not received prophylactic liver therapy. No definite

after total gastrectomy are not included because removal of the stomach was not total. For similar reasons, or because of insufficient data, certain cases of alleged macrocytic anemia after total gastrectomy are excluded 36-41.

After exclusion of patients definitely known to have received prophylactic treatment with liver, 46

information is available whether or not liver was given in the other 19 cases (Table 5).

In the 12 cases with macrocytosis and hyperchromia, a pathological diagnosis of ulcer or gastritis was made in half, whereas none of those with malignant lesions had any evidence of recurrence. Generally speaking, these patients had a satisfactory

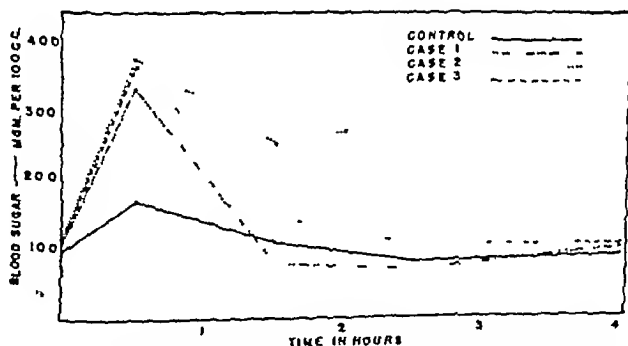

FIGURE 4 Oral Glucose Tolerance Curve following Administration of 50 gm. of Glucose Dissolved in 200 cc of Water

cases remain. Of these, 12 appear to have had blood findings resembling those of pernicious anemia, and 5 others had anemias of doubtful nature.

Another case of macrocytosis and hyperchromia — red-cell count of 3,810,000, hemoglobin of 95 per cent (Sahli), mean red-cell diameter of 8.8 microns and nucleated red cells found on smear — is reported by Ungley 42. This blood picture developed five months after total gastrectomy, but the patient

surgical result, and it seems probable that their diet was adequate. It is noteworthy that 3 cases showed a definite reduction in the red-cell count, with an increase in the mean corpuscular volume, but relatively little decrease in hemoglobin. It is possible that this is the earlier stage of this type of anemia.

Macrocytic anemias seldom occurred less than two years after operation. This finding was also

noted in the studies of similar anemias occurring after less radical gastric resection^{84, 85} Why so long a time is required to develop this blood picture is unknown Schwartz and Legere⁸⁶ recently reported that self-induced relapses in 54 patients who had

have been administered indiscriminately, and special studies like reticulocyte counts and bone-marrow examinations have been few Only if macrocytic anemias that follow total gastrectomy are carefully investigated by the methods used by Meyer et al⁸

*Most of the patients operated on at the Lahey Clinic probably received liver⁸⁴

been treated with liver occurred two to thirty-eight months after cessation of therapy for pernicious anemia They stress the fact that relapse is a highly singular phenomenon that is unpredictable in any given case This individual variation is also seen in the macrocytic anemias after total gastrectomy

The evidence appears to support the statement that an anemia morphologically similar to Addisonian pernicious anemia will develop after total gastrectomy if the patient survives long enough Whether the anemia is truly Addisonian, or whether it is another form of macrocytic anemia requires further study In the past, most patients developing macrocytic anemia after total gastrectomy have been incompletely studied, for the effects of dietary deficiency have not been excluded, liver and iron

can their relation to Addisonian pernicious anemia be clarified

SURVIVAL

A review of the literature to determine the incidence of anemia in patients surviving total gastrectomy for more than three years uncovered so many inconsistencies and forgotten cases that a note on the period of survival following total gastrectomy seems indicated

Until recently, the patient of Zikoff⁸⁷ was considered the longest survival after total gastrectomy for carcinoma, since Finney and Rienhoff⁸⁸ reported her alive four years and eight months after operation Zikoff's article, however, is an early post-operative report, which does not contain any in-

formation concerning subsequent survival. Attention is directed to a much overlooked reference, the Hüntner lecture of 1906, by H. J. Paterson.⁹ In this monograph, he quotes a personal communication from MacDonald, of San Francisco, to the effect that the patients of Brooks Brigham and of MacDonald were alive and well eight and seven years after their operations, which, incidentally, were the second and third successful total gastrectomies reported in the literature. One of the patients studied by us is alive and well ten and a half years post-operatively, whereas the patient described by Poole and Foster⁹ is still alive and well 20 years after the complete removal of the stomach for a nonmalignant condition.¹⁰ These 2 cases appear to represent the longest known survivals after total gastrectomy for malignant and nonmalignant tumors respectively.

SUMMARY

Studies on 2 patients who had survived total gastrectomy ten and three years respectively and on 1 who had survived total gastrectomy, splenectomy and partial pancreatectomy five years revealed the clinical condition of the patients with total gastrectomy alone to be excellent. Considerable dilatation of the jejunum near the esophagojejunal anastomosis was demonstrated by roentgenologic and kymographic methods in 1 case. In both cases, pancreatic enzymes were normal, and fat absorption on a low-fat intake was not significantly impaired. Vitamin A tolerance curves showed an apparently delayed but otherwise normal absorption of the vitamin. Glucose-tolerance tests disclosed an early and marked, but transient, hyperglycemia.

The patient with total gastrectomy, splenectomy and partial pancreatectomy experienced difficulty in maintaining weight. Dilatation of the jejunum was present. Pancreatic enzymes were deficient, fat absorption impaired, and the vitamin A tolerance curve flat. The glucose-tolerance curve showed a hyperglycemia, which was sustained.

Blood studies demonstrated that 2 of the 3 patients developed a macrocytic, hyperchromic anemia two and five years respectively after operation. The other had received prophylactic liver treatment. A review of the literature revealed a high incidence of macrocytic, hyperchromic anemia in patients surviving total gastrectomy for three or more years.

A REVIEW OF SOME RECENTLY DEFINED VIRUS DISEASES*

JOHN F. ENDERS, PH D †

BOSTON

DURING the decade 1920-1930, when I first began the study of infectious agents, it was more or less generally agreed that the era of etiologic discovery, if not definitely ended, was at least in its final stage. The efforts of bacteriologists in the future were to be directed to the more intensive study of the known pathogenic organisms—the number of which would not be materially increased—with a view to defining more precisely their metabolism, their chemistry, the immune reactions that they elicited and the means by which their attack might be prevented or withstood. However, we failed to visualize that rapid extension of its boundaries that was so soon to come! Since 1930 not only have the causative agents of such old and important diseases as yellow fever, influenza and mumps been determined but also the etiology of a large group of other infectious maladies, many of which had been clinically unrecognized, has been established. If the diseases of the lower animals that have been described during the same period are included the number of additions to this area of pathology becomes impressive indeed. To emphasize the fact that the age of etiologic discovery is far from ended, the following fairly complete list of diseases in man is given for which, within the period from 1940 to 1946, either conclusive or presumptive evidence of viral etiology has been presented: primary atypical pneumonia, Reimann's epidemic diarrhea epidemic keratoconjunctivitis, Colorado tick fever, Russian spring-summer encephalitis, equine encephalomyelitis (Venezuelan strain), infectious jaundice, homologous serum jaundice, Dodd-Buddingh stomatitis and diarrhea of infants (final establishment of etiology requires confirmatory experiments), epidemic diarrhea of the newborn (final establishment of etiology requires confirmatory experiments), Fort Bragg fever or pretibial fever, West Nile fever (Africa), and Semliki forest fever (Africa). Indeed, after this list was prepared, a new virus disease was reported by a group of workers in Tennessee.¹ An outbreak of epidemic meningoencephalitis accompanied by vesicular pharyngitis affected over 200 persons, and inoculation of filtrates of nasopharyngeal washings from certain patients into the embryonated egg resulted in the isolation of what is tentatively described as a virus differing from any of the known agents.

It is my purpose to discuss mainly from the etiologic standpoint the first three diseases listed above. Of these primary atypical pneumonia and epidemic diarrhea have been of common occurrence in these regions. Epidemic conjunctivitis has been recognized in New York and the surrounding areas, although it seems first to have been clearly described on the Pacific Coast. As knowledge of it becomes more widely disseminated it is probable that more and more cases will be recognized.

PRIMARY ATYPICAL PNEUMONIA AND MINOR ACUTE UPPER RESPIRATORY ILLNESS

In a small number of patients with primary atypical pneumonia a fungous infection, the rickettsia of Q fever or the viruses of the psittacosis-ornithosis group have been shown to be involved.² But the determination of the nature of the agent responsible for the majority of cases has presented a baffling problem to investigators ever since this condition was recognized as a clinical entity in the years just preceding the war. At that time intensive efforts to reveal a virus in the blood, sputum and nasopharyngeal washings were made. These materials were obtained from patients studied clinically by Bock³ and by Murray,⁴ who were among the first to describe the disease in this area. My results, like those of many others reported at that time and subsequently, were entirely negative. A few investigators, however, claimed to have isolated a virus. Thus, Weir and Horsfall⁵ produced a nonbacterial pneumonia in the mongoose and Eaton and his co-workers⁶ described the propagation of a filterable agent in cotton rats and the embryonated egg. These observations have not as yet been confirmed by other workers.

By 1944 it was therefore obvious to most investigators that the agent of this disease was closely adapted to the human host—perhaps so closely adapted that it could not be established in any other animal species. Accordingly, the Commission on Respiratory Diseases⁷ located during the war at Fort Bragg, North Carolina, undertook experiments in human volunteers with the objective of proving whether the agent was transmissible and filterable. The results of these elaborate and costly experiments leave no reasonable doubt, I believe, that atypical pneumonia in which none of the known bacterial, fungal, viral or rickettsial agents can be demonstrated is due to a filterable virus. In all, three experiments were carried out in which pooled sputums and nasal washings from patients with character-

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 24, 1947.
†Chief, Research Department of Infectious Diseases, The Children's Hospital.

tic cases of atypical pneumonia were inoculated by the respiratory route into human volunteers. In the last two, the subjects were divided into three groups, one of which received material passed through a bacteria-retaining filter, another unfiltered washings and a third unfiltered material that had been autoclaved. A condition compatible with atypical pneumonia was produced in some of the subjects inoculated in all three experiments. For example, in the last experiment, the typical disease was caused in 3 of the 12 men who received filtrate and in 3 of 12 others who were given the unfiltered material. The incubation period following inoculation with filtered material was approximately fourteen days, and that with unfiltered material approximately seven days. None of the 18 men who received autoclaved material (the control group) developed the disease. Since in this last experiment in particular every precaution was taken to eliminate the possibility of spontaneous infection, the results may be accepted as indicating that atypical pneumonia is due to a nonbacterial, filter-passing agent.

It is of great interest, regarding the current epidemiologic views concerning atypical pneumonia, that 10 of the 24 men who received the unautoclaved material developed minor upper respiratory illness of an undifferentiated type, without signs of lung involvement, since it has been the opinion of clinical students of the disease that during epidemics many persons become infected with the virus who do not develop pneumonia but only mild upper respiratory symptoms. It should be pointed out, however, that whereas these results strongly suggest that the virus of atypical pneumonia frequently gives rise to a non-pneumonic type of infection, they do not prove that the same agent is responsible for both diseases, since the possibility of the presence of two viruses in the inoculum was not ruled out.

The Commission also concerned itself with the relation between two other frequent clinical types of acute respiratory illness and their etiologies. Thus, in additional experiments with 42 volunteers,⁸ they inoculated material obtained from a person with symptoms mainly of coryza—that is, those of the common cold and with minimal signs of pharyngeal inflammation. Another group was inoculated with materials from a patient with an infection distinguished from the common cold principally by sore throat and little nasal involvement. The results indicated clearly that both these clinical types of infection could be experimentally transmitted to human beings by means of filtrates of throat washings. The most interesting finding, perhaps, was the difference in the incubation period of the two types of experimentally induced disease. The coryzal syndrome had an incubation period of one or two days—an observation in agreement with earlier work on the common cold by Dochez and others. In contrast, the disease characterized chiefly by inflammation of the pharynx had an incubation period of

five or six days. It will be noted that both these periods of incubation were shorter than that of the experimental atypical pneumonia. Worthy of emphasis, too, is the finding that no immunity apparently resulted from the experimental coryzal infection, since reinoculation within three weeks with active material from patients who had recovered again induced the disease. On the other hand, the pharyngitis virus produced a specifically increased resistance following reinoculation. Neither the common cold nor the pharyngitic syndrome induced immunity against experimental inoculation of material containing the virus of atypical pneumonia. The participation of hemolytic streptococci or influenza virus in either type of infection was satisfactorily eliminated as a possibility.

In concluding this brief discussion of nonbacterial, acute respiratory disease, exclusive of influenza, it can be stated that although knowledge of these conditions is still distressingly chaotic, definite progress has been made toward an ultimate etiologic classification. Certainly, one can be reasonably certain that the nature of the etiologic agent in primary atypical pneumonia has been defined. The infection may be recognized not only by x-ray findings but also, in many cases, through the application of the test for cold agglutinins⁹ or the Thomas agglutination test employing the indifferent streptococcus MG¹⁰. This information on etiology and on diagnostic aids indicates how much progress has been made in a very difficult problem within a short time. When suitable laboratory facilities are available, full advantage should be taken of them by physicians in the diagnosis of suspected cases of this disease.

REIMANN'S EPIDEMIC DIARRHEA

The occurrence of outbreaks of diarrheal disease, usually mild in character and acute in nature and lasting ordinarily twenty-four or forty-eight hours, has long been observed and has been reported in the medical literature from many parts of the world. The common enteric bacterial pathogens have often been conspicuously absent in such outbreaks, which are prone to occur in institutions such as schools, barracks and hospitals. The mild character of these epidemic gastrointestinal disturbances has been mainly responsible for the lack of efforts toward the elucidation of the responsible agent. Clearly infectious in their behavior, such epidemics do not appear to be occasioned by contaminated food, water or milk. This type of illness in adults, interesting enough in itself, has of late attained additional significance because of possible relations to the cause of the highly fatal diarrhea of the newborn that Clifford¹¹ has discussed. Accordingly, it seems pertinent to emphasize the studies in which Reimann and his associates¹² recently described and investigated an outbreak of epidemic diarrhea among medical students in Philadelphia. This epidemic was similar in all respects to many others that have

been recorded. In general, such outbreaks have had the following characteristics:

They tend to occur in the autumn but there are no strictly seasonal limitations.

Children and young adults appear to be particularly susceptible, but no age group is resistant.

The morbidity is high, ranging from 15 to 100 per cent.

Usually, there is no mortality.

The symptoms, which follow an incubation period of about two days in most cases, consist of anorexia, nausea, vomiting, diarrhea, dizziness, aching and abdominal discomfort or cramps. Not all these manifestations, of course, are always noted in the same person.

Fever is exceptional.

Occasionally, there are concomitant signs of mild upper respiratory disease, a fact that has sometimes been responsible for the diagnosis of so-called "intestinal flu." I have had occasion to follow the investigation of two outbreaks of epidemic diarrhea in state institutions during the last few months. In every respect they conformed in epidemiologic pattern and clinical picture to Reimann's outbreak, except that in a few cases of aged and sick patients the disease seemed to be a contributing factor to their deaths.

Because of the failure to incriminate any of the usual vehicles of transmission of enteric diseases of known etiology, Reimann and his associates¹² investigated experimentally in volunteers the hypothesis that this disease was communicable via the respiratory route. Thirty-two healthy young adults were permitted to inhale nebulized garglings obtained from patients with the typical symptomatology, after the material had been filtered to remove bacteria. Similarly, stool filtrates from patients with acute cases were administered in the form of a fine spray to 21 other volunteers. In each group approximately half the subjects developed symptoms of the disease. In most cases those who became ill did so one to four days after inoculation, thus giving evidence of the probable duration of the incubation period. Unfortunately, these experiments were carried out at a time when the epidemic, although definitely on the wane among the general student body, was still active, and since rigorous precautions for isolation were not possible, the results might be questioned. However, when one considers that the incidence of disease among the student body was only 9 per cent, as contrasted with 53 per cent among the inoculated subjects, there can be little doubt that in the majority of cases the disease had been induced by means of bacteria-free filtrate administered by the respiratory route. That the natural mode of transmission is probably by this route is supported by the fact that no symptoms developed

in a number of volunteers who swallowed capsules containing filtrates of garglings or stools.

As yet there has been little work in attempting to isolate a virus in the laboratory from epidemic diarrhea. Reimann and his associates¹⁴ failed to infect young mice and the chorioallantoic membrane of the embryonated egg. Experiments in our own laboratory are now being carried on with the purpose of investigating this problem more intensively. To my mind these observations of Reimann are of much significance not only because they seem to represent the best evidence so far presented that a virus can cause a characteristic enteric disease but also, taken with other recent information, because they strongly suggest that a whole group of similar agents are involved in various clinical types of acute gastrointestinal disorder.

EPIDEMIC KERATOCONJUNCTIVITIS

Epidemic keratoconjunctivitis is a disease that has long been known but in which the etiology has been obscure. First described by Fuchs in 1889, epidemics have subsequently occurred throughout the world. Not until 1941, however, was the disease reported in the United States, where it emerged as an epidemic in shipyards on the Pacific Coast.¹⁵ Since that time cases have been described elsewhere in this country. In the East, outbreaks have occurred in the area around New York City,¹⁶ in Connecticut and in western Massachusetts. It tends to be epidemic in industrial plants but may occur sporadically, and has been shown to be spread in physicians' offices and ophthalmic dispensaries where proper aseptic technique has not been employed.

The disease is characterized by nonpurulent inflammation of the conjunctiva, preauricular lymphadenitis and superficial punctate corneal opacities. There may be accompanying symptoms of headache, malaise and slight fever. The incubation period is unknown in the natural disease, which lasts from two to four weeks or longer. Recovery is usually complete, although in a small percentage of patients keratitis with impairment of vision may persist. Although earlier experimental work pointed to a filterable virus, it was not until the work of Sanders and Alexander in 1942¹⁷ that the etiology was finally established. With conjunctival scrapings of 2 patients these investigators obtained a mild encephalitic disease following the intracerebral inoculation of white mice. More decisive results were obtained after the cultivation of mouse brain containing the virus in tissue culture with subsequent mouse passages. This somewhat unconventional procedure appeared to enhance the virulence of the virus for mice so that intracerebral inoculation was regularly followed by death. But subsequently, in 1945, Maumenee and his associates¹⁸ isolated a strain of virus that was from the outset of high virulence for mice since it regularly killed these animals within three to five days after intracerebral inoculation.

The mouse-adapted strain of this virus was then cultivated in the embryonated egg by Calkins and Bond.¹⁹

The relation of the virus to the human disease was demonstrated in two ways by Sanders and Alexander¹⁷ instillation of a suspension of mouse brain into the conjunctival sac of a volunteer resulted in a modified but typical attack of keratoconjunctivitis, and patients recovering from the disease were shown to develop antibodies that specifically neutralized the virus. Such antibodies were not found earlier in the disease or in a number of normal human subjects. On the other hand, the pathogenicity of the virus for mice was not neutralized by antibodies against lymphocytic choriomeningitis, Theiler's mouse poliomyelitis and serums from patients suffering from nonspecific conjunctivitis or keratitis. These workers also found the virus to be distinct from the herpes virus on the basis of virus-neutralization tests with appropriate antisera. Maumenee and his associates,¹⁸ however, discerned an antigenic similarity between the virus of keratoconjunctivitis and that of herpes. In spite of this discrepancy in the findings of the two groups of workers the viruses are quite distinct, since animals actively immunized against herpes virus have been shown to be resistant to herpes but not to the epidemic keratoconjunctivitis virus. Moreover, significant differences in the size of the infective particles of the two viruses have been determined. The data indicating that the viruses can be distinguished from each other in the laboratory are important because the herpes virus, as is well known, can cause a conjunctivitis with involvement of the cornea that could be confused with that due to the virus of epidemic keratoconjunctivitis, although certain clinical features of herpetic keratoconjunctivitis are characteristic, such as the dendritic processes of the lesion. The lack of epidemic spread of herpetic conjunctivitis also represents an important differential feature. The clinical similarity is close enough, however, so that recourse should be had to a suitably equipped laboratory if a final etiologic diagnosis is to be made. So far as I know, epidemic keratoconjunctivitis has been a rare disease in Massachusetts, but the possibility exists that epidemics may occur at any time.

* * *

Little or nothing has been said above regarding specific prevention or therapy, because there is as

yet little or nothing to say regarding these always pressing concerns. But with the greatly increased interest and activity in the realm of viruses, it is by no means impossible that in the not too distant future one talking about the various categories of diseases exemplified by the infections I have discussed may have a different story to tell.

MEDICAL CARE FOR THE PEOPLE OF MASSACHUSETTS THE CONTRIBUTION OF BLUE SHIELD*

CHARLES G. HAYDEN, M.D.†

BOSTON

THERE are now fifty-seven medical-care plans sponsored by medical societies and operating in thirty-three states. They cover approximately 4,500,000 persons. Fifty-five of these plans are nonprofit, the other two utilize the services of commercial insurance carriers. In the fifteen states that do not have plans in operation, nonprofit plans are being organized in seven, commercial plans are being organized in three, and preliminary discussions are under way in four. This leaves but one state in which nothing tangible is being accomplished.

Much of the credit for this remarkable picture must go to the Council on Medical Service of the American Medical Association, which since its creation in 1943 has not only prompted the establishment of plans in many areas but also given marked impetus to the medical-care-plan movement as a whole.

Although well able to carry on its promotional functions, the Council early realized that it was not in a position to cope with the technical aspects of development and co-ordination. Consequently, about a year ago, it sponsored a meeting of plan executives, out of which came an independent organization known as Associated Medical Care Plans. Between annual meetings of the members, the affairs of this association are directed by a nine-man commission that includes three representatives from the Council on Medical Service.

Although there is necessarily some overlapping of the interests and activities of the Council on Medical Service and the Commission of Associated Medical Care Plans, the Council is primarily concerned with promoting the establishment of plans and determining broad concepts of policy that should characterize the prepayment movement. The Commission, on the other hand, is primarily occupied with the day-to-day problems of plan organization and operation and with interplan relations.

Of the sixty-two nonprofit plans now in operation, or about to operate, forty-one are members of Associated Medical Care Plans, and it is expected that the remaining twenty-one will become members in the very near future. Although not specifically excluded, it is highly unlikely that any commercial plan will be admitted to membership.

With nearly 600,000 persons covered, Massachusetts Medical Service (Blue Shield) is the second

largest and one of the most successful medical-care plans in the nation. In retrospect, the primary reasons for these achievements are not hard to find and may be briefly summarized as follows:

The Board of Directors is made up of one third physicians and two thirds laymen. Lay representation is almost equally divided between the population segments broadly defined by the terms labor and management. In the conduct of a million-dollar enterprise, it is absolutely essential that provision be made for guidance by trained businessmen. Similarly, in any organization that deals directly with hundreds of thousands of persons it is essential that certain of their attitudes be constantly appraised by experts in such matters.

All rules and regulations pertaining to medical relation must be initiated by the physicians on the Board and approved by the Executive Committee of the Council of the Massachusetts Medical Society. It is now generally acknowledged that in any kind of medical-care program, determinations concerning medical matters must be delegated to the physicians involved.

Income limits, below which members are entitled to service benefits without additional charge, must be approved by the Council of the Massachusetts Medical Society. The level at which income limits are established is a direct measure of the willingness of the medical profession to assume a fundamental sociologic obligation on behalf of persons in the low and moderate income groups and therefore has a direct influence on sales resistance and the attitude of the public toward the profession. Consequently, it is of the utmost importance that these determinations be based on enlightened professional self-interest. When Massachusetts Medical Service was established, approximately 80 per cent of the wage-earning population of the Commonwealth was in the under-income category. With increased earnings during the war, this figure fell to 65 per cent, where it remained until recent action of the Council raised the limit for the family to \$3000 and thus restored the original relation, which, incidentally, is becoming recognized as standard for the nation.

Physician participation, initially in the neighborhood of 50 per cent, has steadily increased to its present level of more than 90 per cent. With payments for services by nonparticipating physi-

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 20, 1947.

†Medical Director, Massachusetts Medical Service and Massachusetts Hospital Service member, Commission Associated Medical Care Plans.

cians within the Commonwealth virtually excluded, it is absolutely essential that a large percentage participate and that they be well distributed throughout the Commonwealth, otherwise the plan degenerates into a straight cash-indemnity arrangement

The administrative relation with Massachusetts Hospital Service, Incorporated (Blue Cross) has been eminently successful. Below the policy-making level there is practically no discernible distinction between the two organizations

As presently constituted, Massachusetts Medical Service (Blue Shield) provides benefits only for surgical and obstetric services rendered in the hospital. On June 1, 1947, this program will be extended to include benefits for medical (nonsurgical) services rendered in the hospital and for surgical and obstetric services rendered outside the hospital. Inclusion of benefits for medical (nonsurgical) services rendered outside the hospital is not anticipated in the immediate future because this type of coverage is financially hazardous unless undesirable coinsurance features are imposed or unless subscription rates are increased beyond the present point of public acceptance

Implementation of any program directly affecting the public is bound to arouse a crossfire of conflicting interests. Difficulties both predictable and unpredictable arise. Nevertheless, if such a program is to survive and prosper in a democracy, its difficulties must ultimately be resolved in the interest of the public

Many studies made during the past few years have indicated that the American people favor prepayment of the cost of medical and hospital care. Acknowledging this interest, the American Medical Association and its constituent societies are now committed to the principle of prepayment, with the reservation, however, that it be developed under voluntary auspices. With the imposition of this qualification, the medical profession assumed a tremendous obligation

To meet this obligation, medical societies have set up their own prepayment plans in thirty-one states. In two other states the societies have called upon commercial insurance carriers. The only point of distinction between the prepayment movement as it developed in Great Britain and on the Continent and as it is being developed here is that the

medical profession in the United States has sought to meet its own responsibility without the interposition of a third party imbued with interests foreign to the basic concepts that characterize medical practice. Should a wholesale tendency on the part of physicians to hand over their acknowledged responsibility to commercial carriers at any time develop, it is safe to predict that American medicine will quickly fall into the hands of the Government

Although it may be assumed that medical-care plans sponsored by medical societies will be in operation in all states in the near future, it would be fatal to assume that the obligation of the medical profession will thereby be resolved. To establish a medical-care plan is one thing, to keep it operating on a satisfactory basis is another

Up to the present, Massachusetts Medical Service (Blue Shield), which is one of the older plans, has encountered no serious problems, mainly because the number of plan patients that any given physician may see is not large. However, the picture is now rapidly changing. Present enrollment is in the neighborhood of 600,000 persons, and it seems safe to predict that by this time next year the figure will reach 1,000,000 or more. The result is that previously casual professional relations are becoming less casual as more and more physicians come to realize that by its very nature an expanding medical prepayment plan, while solving many problems, introduces new ones. From his own economic standpoint, for instance, it becomes increasingly incumbent upon the physician to establish a routine that will effectively identify plan patients and establish their income status. Similarly, from the standpoint of the plan patient, a routine of this sort must be developed if confusion and delay, with consequent ill feeling, are to be avoided

Fortunately, the vast majority of problems that arise lend themselves to reasonable solution. Nevertheless, they frequently require professional concessions, which must be made if the program is to accomplish its objectives and satisfy rational public demands. Massachusetts Medical Service (Blue Shield) is an organ of the Massachusetts Medical Society. Its board of directors is elected by the Executive Committee of the Council. Every physician has a direct voice in its affairs through his district professional service committee. Its problems are the problems of the profession, and its success or failure will largely be determined by professional attitudes now in the process of development

REHABILITATION OF THE EMPLOYEE INJURED IN INDUSTRY*

ALEXANDER P. AITKEN, M.D.†

BOSTON

IN THE life of the average workingman there is nothing more serious than the loss of his earning capacity. A serious injury with prolonged disability has far-reaching effects, not only on the man himself but also on his family. Plans for the purchase of a home and for education of his family are uppermost in the minds of most workingmen — plans that may have to be abandoned as a result of an industrial accident. It is only natural, therefore, that a person so injured should look to his doctor for the treatment that will restore him to his job in the best possible condition in the shortest possible time. It is clearly the physician's duty to give his very best from the minute of injury until the patient can return to work.

In the past few years progress in the treatment of traumatic lesions has come largely through the perfection of technique in the handling of the acute emergency. In this regard tremendous strides have been made. Most men who have kept abreast of the literature and who are aware of the modern methods of treatment can handle the acute emergency with competence. Treatment when the emergency is over, however, leaves much to be desired.

All physicians are more or less x-ray conscious and are apt to be most concerned with the roentgenographic appearance of the patient's lesion. However, we are likely to be entirely oblivious of the physiologic, pathologic and mental changes that may be developing in the patient. Failure to recognize such changes, produced by immobilization and enforced recumbency, may seriously delay the recovery of patients who have had efficient treatment in the emergency. Until these changes are recognized they cannot be prevented, and the patient's convalescence will be extended. Inadequate after-care is one of the great weaknesses of present-day surgery.

The first of the complications or changes that must be prevented is atrophy. When a patient is forced to remain in bed, all the tissues, particularly skeletal muscle, undergo atrophy. The second change is joint stiffness. The longer the period of recumbency, the more extensive atrophy and joint stiffness become. We have all seen patients too weak to sit up and too stiff to walk when their injuries have sufficiently healed to allow them to do so. This leads to further recumbency and the development of a vicious circle. Unfortunately this

condition is not uncommon and is a definite reflection on present-day treatment. General body and muscular tone can be maintained and joint stiffness prevented if patients perform simple exercises while in bed. There is usually no reason why such exercises cannot be performed in parts remote from the site of injury. The exercises not only benefit the patient physically but also help develop a feeling of well-being and, of utmost importance, help to bolster morale. Such exercises must not be left to the patient. The physician must see to it that these exercises are done, and done intelligently. By such means, the period of disability can be cut down and the patient's physical condition improved when he is ready to become ambulatory.

When it is necessary to splint a part, atrophy is much more rapid and extensive, and joint stiffness more likely to occur. Therefore in splinting, only the minimum immobilization must be used. Parts uninvolved must be kept free so that they can be exercised. One of the most troublesome complications of fractures of the upper extremity — the "frozen shoulder" due to carrying the arm in a sling — can be readily avoided if the patient simply lifts his arm over his head in flexion and abduction several times a day. This can be done without risk in fractures, once the part is adequately immobilized.

If there is persistent swelling of a part, the excess lymph in the tissues leaves a deposit of fibrin that, in time, is replaced by granulation tissue. Granulation tissue is scar tissue, and scar in the vicinity of a joint means loss of motion particularly if the joint requires immobilization. This is of the utmost importance in injuries of the hand and wrist, in which swelling of the fingers is likely to occur. When such injuries require splinting, only the minimum splinting must be used. Casts applied for injuries of the forearm and wrist should not extend beyond the distal palmar crease, so that the fingers can be mobilized. When fingers must be splinted the position of flexion should be used whenever possible to put the collateral ligaments of the fingers under tension. To allow the ligaments to stiffen and contract in the position of extension means long and tedious work in the restoration of flexion. About 25 per cent of cases at the Liberty Mutual Rehabilitation Center are hand injuries, and many of these patients are under treatment for stiffness of the fingers that, with proper immobilization, could have been avoided.

When the lower extremity requires immobilization, muscle tone can still be largely preserved by

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 20, 1947.
†Medical Director, Rehabilitation Center, Liberty Mutual Insurance Company.

the simple process of muscle setting within the splint or cast. This can be done without jeopardizing the healing process in all conditions, with the possible exception of fresh tendon sutures.

By exercising the body as a whole while the patient is in bed and by exercising uninvolved parts and by muscle-setting exercises while he is in splints, much can be done to preserve general and local muscle tone and joint mobility during the period of recumbency or immobilization.

When the patient is freed of all apparatus and is ambulatory the job is by no means over. This is in all probability the most critical period of all, because failure to use the injured part can still nullify all the good work done in the period of immobilization. When a patient is at home he is no longer under complete supervision and is apt to neglect his exercises. Trips to the doctor's office three times a week for baking and massage make a dangerous rut for the patient to get into. Between these trips he is likely to do nothing for himself and to let the physician or a physiotherapist do the work for him.

Patients must be made to understand that the doctor or his physiotherapist can aid them in the restoration of strength and motion, but that the actual work must be done by themselves. Exercises must be performed even though they cause some discomfort. However, it is the duty of the physician to make sure that a definite course of action is adopted and understood. The patient must know exactly what exercises he is to do, how long he must do them and why he is doing them. Too often, progress is slow because the patient does not do the exercises properly if at all. This is often due to the fact that the doctor has not given sufficient instruction and has not checked to see that the instructions have been carried out. Routine gymnastic exercises are dull and uninteresting, and often do not accomplish the desired result. Exercises in the form of work therapy are much more beneficial. A patient with a saw and hammer can accomplish more for himself in one week than all the baking and massage can perform in months. Work or occupational therapy is a form of treatment that has been completely overlooked and that everyone interested in the treatment of traumatic lesions must learn. Occupational therapy does not mean the making of leather belts, pocketbooks and so forth, which have a place in some conditions but are chiefly diversional and of little value to the average worker, but actual work designed to restore to the patient motions essential in his trade. Frederick J. Cotton once said, "The best way to restore a bricklayer to his job is to make him lay bricks." This statement is undeniably true, but such therapy is not always so simple as it sounds.

Patients who have had prolonged and painful disability are apt to suffer from mental depression or loss of morale. Failure to notice improvement favors the development of many psychogenic factors,

particularly an anxiety state. Fear of being unable to return to their regular work and fear that they have lost their jobs after a prolonged convalescence are common causes of mental depression and loss of morale. This state is aggravated by domestic and financial difficulties, brought on by the loss of earning power. Occasionally, this condition is precipitated or aggravated by the development of the menopause. Such patients are extremely difficult to rehabilitate. They need encouragement and must often be convinced that they are not quite so badly off as they think. For such a person there is no better treatment than work therapy.

Dissatisfaction with present methods of treatment and encouragement offered by the rehabilitation program developed in England during the war brought about the establishment of the Rehabilitation Center by the Liberty Mutual Insurance Company in June, 1943. In the past four years we have become convinced of the value of a combination of physiotherapy and occupational therapy, and the decided advantage of keeping the patient busy all day long for five days a week.

When a patient is admitted to the Center a complete appraisal is made. The exact extent of the injuries is determined. If it is believed that he can be rehabilitated, that further surgery is not indicated and that the general physical condition is satisfactory, treatment is started.

Usually, the patient is sent first to the physiotherapy department, which is completely equipped with the usual armamentarium of infrared lamps, diathermy, whirlpool baths, paraffin baths, stall bars, chest weights, Kanavel tables, graduated stairs, resistance bicycles, rowing machines and so forth. Here he is placed on daily exercises that are performed under supervision.

When he has improved sufficiently he is sent to the occupational-therapy department, where he is given work to exercise the disabled part. Tools and sanding blocks are constructed to fit the individual needs of the patient. All work is planned and supervised. Care is taken not to exceed the fatigue point. At first only light or sedentary work may be done. As the work tolerance increases, the work load is increased. Since most of these patients are unskilled, woodworking is the chief means of work therapy. No motor-driven tools are used. Jig saws are operated by sewing-machine or bicycle jigs. For ankle injuries the sewing-machine jig and for knee injuries the bicycle jig are used. Foot-operated grinding wheels are also of value. For shoulder injuries suspension slings aid in elevation of the arm. When a shoulder has improved sufficiently a hand-operated printing machine is of value. Painters are allowed to paint and thus to exercise their shoulders, hands and wrists. There is a complete machinist's outfit. Logs for sawing and a sand pit are used to build work tolerance in laborers. Hand saws, planes, files and the usual carpenter's equip-

ment are of great value in restoring lost motion and muscle power, especially in the upper extremity. To keep the patient's interest, definite work projects are created. The building of such objects as end tables, sewing cabinets, tool boxes, rocking horses, carts, chairs and magazine racks holds the patient's interest. Knot tying, rug making, modeling in plaster and work carving are of value in hand cases. All work can be done at any level and in any plane,

psychologically. It is not uncommon for patients to say, "If I can do this work I can do my own." Most patients, convinced in their own minds that they can return to work, need no further stimulus to do so.

The following statistics give some idea of our success (Table 1). In the past four years 666 cases have been treated. Of this number there were 540 male and 126 female patients. The average

TABLE 1 *Results of Therapy at Rehabilitation Center, Liberty Mutual Insurance Company from June, 1943 to April, 1947*

TOTAL PATIENTS	MALE PATIENTS	FEMALE PATIENTS	AVERAGE AGE		AVERAGE INTERVAL FROM INJURY TO ADMISSION	AVERAGE PERIOD OF TREATMENT	PATIENTS RETURNED TO WORK	
			MALE PATIENTS	FEMALE PATIENTS			NO.	PERCENTAGE
666	540	126	37 46	37 43	mo 6.5	da. 42	368	65

so that any lost motion and any atrophied muscle group can be restored.

When a patient has reached his work tolerance he is allowed to rest. At that time he can listen to the radio and, especially in the summer months, to the ball games.

After the rest period he is sent to the recreational therapy department. He may play pool, ping-pong, horseshoes, darts, checkers and so forth. Recreational therapy is also designed to aid in the restoration of lost motion. For example, checkers may be played on the floor, on a table or on the wall. Ping-pong has been found to be of considerable value in the training of patients with upper-extremity amputations. The agility that can be developed in a short time by this means is remarkable.

The patient, it can be seen, is kept busy all day long for five days a week. The building of articles in the workshop is a tremendous stimulus and does much to raise morale. Patients become so engrossed in their work that they must be carefully watched so that they do not become fatigued. Women are as enthusiastic as men. A spirit of competition is developed between patients with similar injuries. Disgruntled and discouraged patients soon enter into the swing of things and rapidly lose their complaints. Under such a regime most patients make progress both physically and

age is higher than one would expect, being forty-six years for men and forty-three years for women. Most of these patients had multiple and serious injuries. With such injuries, in this age group, the earlier treatment is started, the better the result. In the average case, however, six and a half months had elapsed between the date of injury and admission to the Center. Much valuable time had thus been lost. Atrophy, joint stiffness and loss of morale have usually been well advanced and have been serious handicaps to overcome. Despite this fact, however, 368 patients, or 65 per cent of all patients admitted, have returned to gainful employment. The average length of treatment required has been forty-two days.

Considering the seriousness of the injuries, the age of the patients and the extent of the complications produced by the lack of efficient treatment for six and a half months, it is doubtful that many of these patients could have been rehabilitated by any other means.

Our experience has convinced us of the value of a combination of physical therapy and early work therapy. With the education of the medical profession in the procedures of treatment and after-care described above, it is believed that a far greater number of seriously injured workmen will be restored both to industry and to their families.

MEDICAL PROGRESS

CUTANEOUS MEDICINE

JOHN G. DOWNING, M.D.*

BOSTON

THE skin pictures the general health of the patient much better than any other organ. Age is reflected in the pink bloom of infancy, the oiliness and pasty appearance of adolescence, the disfiguring yellowish spots and telangiectasia of middle age and the wrinkled, thin, overstretched and dry appearance of old age. Physicians of previous generations trained their powers of observation and palpation and carefully studied changes in the skin and mucous membranes, many diagnoses of systemic diseases resulted from their keen perception. Today, physicians fail to make use of these facilities and depend too much on mechanical devices and laboratory procedures, many of which are irrelevant or unnecessary, they piece the data together like a picture puzzle.

Fortunately, many clinicians exercise their powers of observation of the skin, for they have learned that such study yields important clues in the diagnosis of systemic disease. Bacteriologists, pathologists, roentgenologists and even anatomists are showing increased interest in dermatology.

An anatomist states that a clinician displays keen clinical discernment when he regards the skin as an index to visceral change as well as subject to dermatologic conditions. To adopt this point of view is to accept the embryologic fact that the skin is an exposed part of the depressed central nervous system or, conversely, that the central nervous system is a depressed part of the skin. Thus, itching or seborrheic dermatitis may be due on the one hand to a specific dermatologic condition and on the other hand to an inherited predisposition of the autonomic nervous system, the gonadal system or the central nervous system. It is this developmental point of view that makes possible the consideration of the skin as an integral part of the organism.¹

No one believes that systemic disease can be diagnosed entirely from the skin, but careful observation can be extremely valuable. Redness of the face may suggest an irritable heart, capillary and arterial pulsation, an aortic insufficiency, cyanosis of the face, a paroxysmal tachycardia, malar flush, a yellowish forehead and blue lips, a mitral stenosis, and petechial spots and pinkish, tender macules on the fingers and toes, an endo-

carditis. The earthy hue of the skin tinged with blueness suggests an emphysema.

Many a systemic disease produces a cutaneous change in the initial or final stages. Many a clinical report starts with the statement that the patient first noticed spots on the skin. These occur so frequently and disappear so rapidly that they may have no clinical significance, except to suggest a certain category of disease, especially the infections. In fatal diseases the skin may give the first warning, as in pruritus or the pigmentary eruptions often seen with internal malignant tumors. Later, the inflammatory lesions may precede metastases. A patient under observation following extirpation of the vulva for removal of a cancer showed nodules and later small bullae preceding a necrotic crusted center that histopathologically revealed carcinoma-tous changes.

The dermatologist has known for centuries that, apart from the dermatitides due to chemical irritants, parasitic infestations and bacterial and fungous infections, most cutaneous diseases are associated with systemic disturbances and that many systemic diseases affect the skin. A dermatologist must have the diagnostic acumen of the internist as well as the patience and therapeutic skill of the "externist." He realizes that treatment must be not only local but also systemic if the contributing or precipitating cause is to be removed.

GENETICS

Abnormalities due to defects of the germ plasm may manifest themselves very early. In albinism a deficiency in pigment may be complete or incomplete. Xeroderma pigmentosa may be suspected by the photophobia noticed in the first few weeks of life and later by erythema, pigmentation, freckles, atrophy, telangiectasia and malignant growths. Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber's syndrome) may affect several members of a family.²

Photodermatitis, with or without circulating hematoporphyrin, is receiving considerable discussion, and it is now fairly well recognized that the porphyria is the result and not the cause of the dermal sensitization.³

Lipoid proteonosis is a familial disease first described in 1929 by Urbach.⁴ It begins in infancy,

*Professor of dermatology, Tufts College Medical School and Boston University School of Medicine

with hoarseness and inability to cry. Various skin-colored, nodular, hyperkeratotic or warty lesions appear on the face, extremities and mucous membranes. Hypertrophic plaques may be present on the elbows and knees. Diabetes is sometimes associated with this disease. The blood lipoids are essentially normal, but there is a disturbance of the phospholipids.

I have seen xanthoma tuberosum multiplex in more than one member of a family. It is due to a hypercholesteremia of the blood, and the patient usually presents yellowish nodules on the buttocks and extensor surfaces. Other members of the family may have diabetes or hypercholesteremia, or both.

Disturbances of the elastic tissue manifest themselves in hyperelasticity and fragility of the skin, hyperelasticity of the joints, pseudo-tumors following trauma and subcutaneous nodules (cutis hyperelastica, Ehlers-Danlos syndrome), and deficient elastic tissue is seen in epidermolysis bullosa. This condition may vary from a mild disturbance of the skin with the occasional bullae following trauma to a severe type with not only cutaneous and mucous membrane lesions but also loss of hair and low intelligence. It may produce such severe systemic disturbances as to mislead dermatologists into describing the disease under another name.

Danbolt and Closs⁸ classified 2 cases by the title "akrodermatitis enteropathica" and attributed the affection to disturbances of the gastrointestinal tract. The disease is characterized by a pustulous dermatitis, which is frequently familial and appears in early childhood, often after weaning. The dermatitis is preferentially located around the natural openings of the body and on the protruding parts of the head, trunk and extremities (hence the term "akrodermatitis"). The terminal phalanges of the fingers are swollen, and there is pustulous paronychia and atrophy of the nails. Furthermore, there are total alopecia, photophobia and blepharitis and sometimes affections of the mucous membrane of the oral cavity (papillomas of the tongue). The disease tends to be chronic, with recurring exacerbations, during which there is diarrhea with foamy, foul-smelling, pale yellowish-gray stools. The calcium and phosphorus content of the urine is pronouncedly diminished.⁸

The above disease is the severe type of epidermolysis bullosa originally described by Wende⁹ in 1902, when he reported a case presenting unusual features. The chief characteristics were as follows: evidence of formation of vesicles and blebs at points subject to trauma and irritation, marked infiltration of the skin after the lesions subside, arrangement of the bullae in concentric patches, decided changes in the nails, lack of hair growth on the scalp and absence of eyelashes and eyebrows, and general tenacity of the skin. I have observed 2 children with this disease both of whom died. One showed pathogenic yeast cells on the peroral and perianal skin.

Keratosis follicularis (Darier's disease) has received more than passing interest because of claims for cure by the administration of vitamin A. I have observed no such cure in my cases, although all patients showed temporary improvement. This disease, which is transmitted by a single dominant, is usually limited to two generations because of infertility.

Thannhauser⁷ disagrees with Cole's diagnosis of congenital ectodermal dysplasia associated with congenital cataracts. The former believes that the cases described are examples of Rothmund's syndrome due to defects of the entire germinal plasma. Cole⁸ retaliates by citing Thannhauser's report of a typical anhydrotic type of ectodermal dysplasia with low fasting blood sugar, a flat sugar-tolerance curve and low blood pressure (disturbance of the adrenal medulla). Roentgenograms showed exostoses of the tables of the skull.⁷ Osseous tissue is of mesodermal origin, and this case was not one of purely congenital ectodermal dysplasia of the anhydrotic type. Cole⁸ states that he had difficulty in putting such a case under the proper heading from the developmental standpoint if the term "congenital ectodermal dysplasia" is to be used. Good proof of this contention is afforded by the fact that it is difficult to separate the ectoderm from the rest of the anatomy.

Carleton¹⁰ described a case that was stated to be one of poikiloderma vasculare atrophicum, associated with cataracts (Rothmund's syndrome). Scleropoikiloderma has been mentioned as one of the characteristics of Werner's syndrome. Thannhauser,¹⁰ however, believes that the features of the skin changes are different in both syndromes. In Werner's syndrome the most striking characteristic is tightening of the skin over the underlying structures, which are very poor in subcutaneous fat tissue. Ulcers develop mainly on the points of pressure on the heels and toes, over the ankles and especially over the Achilles tendon.

Moehlig¹¹ reports a case of progeria (premature old age) with severe dwarfism and congenital cataracts in a five-year-old boy who, although mentally retarded, had an unusual talent for music. This condition (Werner's syndrome) is seen in adults, and the cases are thought to be due to multiple germ defects.¹¹

Neurofibromatosis (Von Recklinghausen's disease) has been traced by Frank¹² through five generations. This is a familial disease in which the defect may be transmitted in the same pattern — namely, one family showing areas of pigmentation and others, tumors of various size present also in the peripheral nerves. It may be associated with alopecia, feeble-mindedness, epilepsy and dementia praecox. The pathogenesis of osteitis cystica localisata and disseminata is closely related to neurofibromatosis. Recklinghausen and its osseous manifestations.¹² Von Recklinghausen's disease is a fairly common

one, which manifests itself in many strange combinations — for example, pigmentation and scoliosis. Its etiology and pathology are still open to discussion. Bourneville's disease occasionally resembles neurofibromatosis. The patient shows reddish, warty tumors, with feeble-mindedness or epilepsy. The tumors on the skin are of the adenoma sebaceum type, and these lesions may appear in the brain, heart or kidneys, resulting in death.

ENDOCRINES

Many dermatologic manifestations have been attributed to endocrine dysfunction. A definite relation has been established in a few but has not been proved in others. The former are those associated with Addison's disease, adrenal tumors, Simmonds's disease, Cushing's syndrome, Frölich's syndrome, the Lawrence-Moon-Biedl syndrome and pancreatic disease. The others range from urticaria to psoriasis. As the result of improvement coincident with or subsequent to hormonal therapy, entities ranging from hypertrichosis to lupus erythematosus have been considered as due to endocrine diseases. Many apparent cures have not been corroborated.

Acne occurs with sufficient frequency in conjunction with changes in the endocrine system — as at adolescence, or with tumors of the adrenal cortex and arrhenoblastoma and also during the administration of androgens — to postulate a relation, but therapy as the result of these observations has not been too successful. Pruritus vulvae, kraurosis vulvae and leukoplakic vulvitis are apparently related to estrogen deficiency, but the clinical response is not startling. Hyperkeratitis (keratoderma) of the palms and soles associated with menopause may respond dramatically to sufficient estrogens. The pigmentation of the skin and mucous membranes in Addison's disease is characteristic and clears with suitable therapy. Calcinosis, local or generalized, may appear with hyperparathyroidism. Many cutaneous lesions have been attributed to diseases of the thyroid gland.

The dermatologist may be the first to diagnose myxedema. First consulted for loss of hair, he may note the dry, yellowish, waxy appearance of the skin, with extensive telangiectasia on the cheeks producing abnormal redness. The hair is dry, brittle and sparse, with considerable loss of the eyebrows, especially at the outer third. A lowered basal metabolic rate and a high cholesterol content confirm the diagnosis. Lange¹⁴ states that the presence of edema in the skin of patients suffering from myxedema and the tendency to generalized serous effusions are so far physiologically unexplained. Five cases of myxedema all showed a marked increase in capillary permeability. With thyroid therapy the permeability rapidly returns to normal, simultaneously with a marked diuresis.¹⁴ Amersbach and Kane¹⁵ reported that localized myxedema of the tuberous variety developed in a

patient who had been suffering from exophthalmic goiter for four years and who had persistent hyperthyroidism, despite protracted therapy, including two thyroidectomies.

Pillsbury and Stokes¹⁶ have described circumscribed forms of the disease. They analyzed 22 cases in the literature and 1 case of their own of circumscribed myxedema of the skin, and divided them into two classes: those characterized by nodular infiltrations variously distributed on the face, arms, back and scrotum, and those in which the manifestations of the skin are invariably associated with exophthalmic goiter. A tuberosc nodular or papular type and a plaque type of myxedema of the skin involving the pretibial region are recognized.

O'Leary¹⁷ reported a number of cases of localized solid edema of the extremities in association with exophthalmic goiter. In the majority of cases circumscribed myxedema follows thyroidectomy, appearing simultaneously with the signs and symptoms of recurrent hyperthyroidism. Sunseri¹⁸ agrees that it may develop before thyroidectomy or before or during the active manifestations of thyroid intoxication.

The assumption that the thyroid hormone plays a role in the healing of wounds was corroborated by the fact that wounds heal poorly and sometimes not at all in myxedematous patients. Eppinger¹⁹ first used aqueous extracts of thyroid gland mixed with lanolin, and then found that pulverized thyroid substance simply strewn into the wound was quite as effective. He believes that many torpid cutaneous ulcers are due to local myxedema.

I have noted an extensive isinglass scaling on the anterior aspect of the lower legs of several women with hypothyroidism. In hyperthyroidism the dermatologist may observe a markedly flushed, terrified, emaciated person whose skin is soft, oily and moist, hyperhidrosis and urticaria may be the chief complaints. Lichen planus with recurrent attacks associated with exacerbations of hyperthyroidism was reported by Ebert and Otsuka.²⁰ A patient with hyperthyroidism may be so sensitive to sunlight that exposure of a few minutes produces severe reddening of the skin and blistering.

Just as the appearance of the patient with myxedema is easily recognized by the physician, so also is that of the acromegalic patient. The skin of the sufferer from pituitary dysfunction, however, may be raised in folds, especially in the scalp, causing cutis verticis gyrata. Weber²¹ stresses this relation and tabulates 12 cases. The hair is thick and coarse, as is the skin, which may be pigmented and freckled owing to melanin, especially in women. The plethoric skin, together with reddish or purplish abdominal striae, and painful adiposity should suggest Cushing's syndrome.

Within the past two years I have seen 2 cases of Simmonds's disease (pituitary cachexia), 1 in a

man, although most cases occur in females. Before death the patient showed complete loss of hair. Although he was in his late forties, the skin was smooth, thin and as delicate as a baby's, with a pale yellowish waxy color. The other patient showed a dry, coarse skin typical of hypothyroidism, with sparseness of the hair and with vegetating, crusting and scaling of the eyebrows, nose and lower legs. The plaques on the lower legs were finally cast off like pieces of bark from a tree. The diagnosis was made by laboratory findings, and therapy resulted in remarkable recovery.

Without corroboration, many diseases, including furunculosis, acne and psoriasis,²² have been attributed to disease of the pancreas. A routine urinalysis is a necessity for a complete dermatologic diagnosis when there is only the complaint of pruritus. Deficiency of the islets of Langerhans may result in many cutaneous entities, such as necrobiosis lipodica diabetorum, xanthomatosis diabetorum and hemochromatosis and such nonspecific manifestations as gangrene, ulcers and bacterial and *Mollitia* infections.

Urbach²³ has recently suggested the term "skin diabetes" to designate the syndrome of "therapy-resistant skin disease (generally presenting the clinical picture of furunculosis, sweat gland abscesses, eczema, pruritus), high fasting skin sugar level together with a normal blood-sugar curve, and pronounced improvement of the dermatosis, as well as fall in high skin sugar level on a low carbohydrate diet, sometimes combined with insulin." His conclusion is as follows:

Quite aside from the question as to whether or not cases presenting independent cutaneous glycohistechia are actually to be regarded as cases of skin diabetes, it may be safely said on the basis of clinical experience that a diabetic diet should unhesitatingly be tried in cases of therapy-resistant skin diseases such as furunculosis, eczema, or pruritus, even when the blood-sugar tolerance test is normal.

Sheppard²⁴ has reported stomatitis, burning, ulceration, dryness and many tongue symptoms.

ALLERGY

Allergy has become a too popular word in dermatology and medicine. It is time to review von Pirquet's²⁵ original article, in which he states

We need a new, general and unambiguous word for the change of condition which the organism undergoes through contact with some organic, animate, or inanimate poison. The vaccinated person is in a different relation to the pox or lymph, the syphilitic, in a different relation to the syphilitic organism, the tubercular person in a different relation to the tuberculin and the person injected with serum in a different relation to the serum than are the individuals who have not yet come in contact with the agent concerned. Nevertheless he is still far from being sensitive. All that we can say of him is that his capability of reaction is changed. For this general idea of changed reaction capability I propose the word allergy (allot designates the deviation from the original setup, that is, the deviation from the normal conduct). The vaccinated one, the tubercular, the person injected with the serum are

with regard to their respective foreign bodies allergic. A foreign body, on the other hand, which influences the organism by means of incorporation (one or several times) to a change of reaction is an allergen. To the allergens belong not only the poisons but also the numerous albuminous bodies which cause no antibody formation but cause hypersensitivity. All indices of infection sicknesses which are followed by immunity are allergens.

Several years ago, after listening to a symposium on allergy and dermatology, I defined allergy as follows: "In the field of practical dermatology, allergy is an intellectual hobby limited only by one's powers of expression, oral or written."²⁶ The term "allergy" may be accepted according to the definition of a specific altered capacity to react if the causative factors can be specified, as in cases of bacterial infections.²⁷ "Allergy" is rapidly becoming a huge wastepaper basket into which many diseases of unknown etiology are being tossed — a catch-all phrase like "eczema" or "rheumatism."

Periarteritis nodosa, a disease of unknown etiology, is now attributed to allergy or hypersensitivity because after a single positive exposure the patient died and autopsy showed arterial lesions similar to those of periarteritis nodosa. It is interesting to read the various editorial comments in the *Journal of the American Medical Association*. One of these states that periarteritis nodosa has generally been regarded as a rare disease, probably infectious, which almost always ends fatally and has rarely been diagnosed in vivo.²⁷ The chief histologic feature is a necrotizing lesion on the arterial wall with a surrounding inflammatory reaction. The diagnosis is difficult except in the rare cases that exhibit the characteristic subcutaneous nodules with the characteristic histologic changes in the blood vessels. Periarteritis nodosa has been attributed to syphilis, to a filterable virus, to various infections, to toxic injuries and to disease of the central nervous system. Gruber was among the earliest investigators to suggest that the condition was due to hypersensitivity.²⁷ The recent observations of Rich²⁸ and of Rich and Gregory²⁹ add support to this theory.

In 1942 Rich²⁸ reported autopsies on 5 patients who had had serum sickness shortly before death, in all of whom vascular lesions characteristic of periarteritis nodosa were demonstrable. None of the patients had any symptoms suggestive of periarteritis prior to the acute terminal illness, and all the vascular lesions were fresh. Similar vascular lesions were demonstrated in 2 patients who had had reactions to sulfonamide therapy.²⁸ Rich concluded that vascular lesions of the periarteritic type can be a manifestation of the anaphylactic type of hypersensitivity.

In the following year Rich and Gregory²⁹ reported the experimental production of similar lesions. Rabbits were sensitized with one or more large doses (10 cc) of horse serum. All the animals on skin test the immediate anaphylactic

type of hypersensitivity, some developing Arthus reactions with necrosis. They were sacrificed at periods ranging from seventeen to twenty-six days, and the majority showed arteritic lesions characteristic of various stages of periarteritis nodosa. In an extension of this experiment the authors³¹ found in the hearts of 11 of 36 similarly sensitized rabbits lesions that reproduced closely the five supposedly pathognomonic features of acute rheumatic carditis. Caution in interpreting these experiments is suggested by the reports of periarteritis developing in rats and dogs made hypertensive by clamping of the renal artery³² or by wrapping of the kidney in silk.³³

Another editorial states that the function and purpose of the allergic reactions are receiving close attention and that some attempt is being made to apply the result of laboratory experiments to patients.³⁴ The increased understanding of tissue reactions is a step forward. Concerning the allergic subject, however, it is not yet certain that the variation from the normal depends on anything more than a quantitative change.

An interesting clinical entity was described in 1932 by Loeffler. Miller³⁵ reported a case and stated that only 4 such cases had been reported in this country. The most important criteria for diagnosis, he asserted, are the symptoms and signs of pulmonary disease, the extent and character of pulmonary involvement, the transient character of the pulmonary shadows, eosinophilia and seasonal and sex variation. X-ray examination usually reveals a more extensive pulmonary involvement than was suspected from the clinical examination. The eosinophil count usually ranges between 15 and 35 per cent but has in some cases exceeded 60 per cent. The pathology of this disease is unknown, since no clear-cut fatal case has come to autopsy. The etiology of the disease is also uncertain. Most authorities describe the syndrome as an allergic response of the pulmonary tissue that may be induced by various allergens.

There must have been deaths later from this disease, for it is stated that the changes in the few cases examined after death appear to support the allergic explanation.³⁶ It is further pointed out that granulomatous processes in other organs, such as eosinophilic granuloma of bone, may also be allergic.³⁷

In Weidman's excellent article on eosinophilic granulomas of the skin he considers their relation to Loeffler's syndrome. The journals of tropical medicine are outstanding in their reports of this disease because animal parasites (ranging from ascaris to ameba) are the occasion for the eosinophilia. Hodes and Wood³⁸ called it "tropical eosinophilia." Indeed, the injection of extracts of ascaris has proved the eosinophilogenous role of these parasites through the mechanism of allergy. The interstitial tissue (not the bronchi) is the shock organ.³⁹ Animal parasites, however, are not always demonstrable, notably in the cases in Palestine and those in which cutaneous

manifestations were associated. Cutaneous involvement has been established by Lyon and Kleinhans,⁴⁰ who reported 20 cases in Jerusalem in six months, although several patients did not exhibit pulmonary lesions. They cited other authors who spoke of "eosinophilic erythroedema," "eosinophilic disease with cutaneous manifestations" and eosinophilia in the sternal bone marrow in addition to the other lesions. Substantially, the dermatosis is a diffuse erythema multiforme perstans in large patches, affecting both the skin and the oral mucosa, and often migrating. In any event, a new message has come to dermatologists. Patients with persistent erythema multiforme lesions (including migrating ones) demand study regarding the possibilities of Loeffler's syndrome.^{41, 42} Pujol⁴³ reports a case with dermatitis in Brazil.

I believe that if physicians keep this disease in mind many cases will be found. Within six months I have seen 2 cases that suggested it. The biopsy in each case showed no eosinophilia. The first patient was a three-year-old girl with a history of a more or less generalized eruption of three weeks' duration. The eruption consisted of raised, circinate plaques involving the arms, lower trunk and legs. Superimposed on several of the plaques were vesicles and small bullae. The patient also had a history of frequent asthmatic attacks and showed pediculosis of the scalp. The white-cell count was 17,500, with an eosinophil count ranging around 24 per cent. X-ray examination of the chest showed extensive mottling.

The second patient, a twenty-three-year-old man, was admitted to a tuberculosis sanatorium because of an x-ray diagnosis of tuberculosis. Repeated x-ray examination suggested sarcoid. Six weeks later the x-ray findings were essentially negative. The first examination revealed a half-dollar-sized erythematous wheal on the lower portion of the chest. This persisted, and three weeks later similar lesions appeared on the left arm, forehead, abdomen, buttocks and thighs. A diagnosis of erythema multiforme perstans was made. Three months later the eruption had disappeared, leaving pigmented areas. Laboratory studies were negative except for a white-cell count ranging from 13,500 to 29,000. There was a persistent increase in the percentage of eosinophils, ranging at times from 20 to 55 per cent. Sternal puncture showed marked eosinophilia, and nasal polyps removed were markedly infiltrated with eosinophils. This case is interesting because it has been stated by some authors that the roentgenographic appearance of the process is often not unlike that of tuberculosis.⁴⁴

RHEUMATIC DISEASES

According to Campbell et al.⁴⁵ erythema multiforme and erythema nodosum are not specific lesions of rheumatic fever. The most frequent type of eruption is found on the trunk, upper arms and legs.

The lesions, which are macular and from 1 to 2 cm in diameter (occasionally larger), appear as bright-pink circinate or gyrate areas. They become more prominent after a few minutes' undressed exposure and vary from day to day. Red, elevated, edematous plaques may be seen over the affected joints. The cutaneous lesions appear after the joint manifestations. Subcutaneous nodules attached to tendons, ligaments and fascia over the elbows, knees or other joints may remain for several weeks and suggest a severe infection. Purpura and urticaria are not infrequent findings. Skin lesions in rheumatic fever do not help in deciding when rheumatic activity ends, they are merely acute manifestations occurring in a persistent disease.

Perry⁴⁶ studied 112 patients — 38 males and 74 females. The material reviewed offers little support to the theory that erythema nodosum is a manifestation of acute rheumatic fever. Perry agrees with those who have held that erythema nodosum must be regarded as the result of a nonspecific reaction to a variety of infections or toxic agents and that it is not a specific disease. It is clear, however, that these agents give rise to the syndrome only in patients constitutionally predisposed to it.

The relation between psoriasis and arthritis appearing before, during or after the appearance of the psoriatic lesions is a well established finding. The arthritis may respond to proper treatment of the psoriasis.

In a recent article Mallory⁴⁷ cites the hypothesis advanced by Rich that the lesions of periarteritis nodosa and rheumatic fever are the result of anaphylactic hypersensitivity.⁴⁸

Sargent⁴⁸ reports 3 cases of Reiter's syndrome, the etiology of which is completely unknown. This disease of dramatic proportions is characterized by extensive lesions of the joints, mucous membranes and skin. It is exceedingly protracted in its course sometimes reactivating after prolonged periods of remission, but tending to spontaneous recovery. It is utterly refractory to all known treatment, except perhaps as it may be mildly benefited by such indirect stimulative and supportive methods as local physiotherapy, fever therapy and whole-blood transfusions.

Reiter⁴⁹ first described this disease as being characterized by arthritis, urethritis and conjunctivitis not caused by gonorrhea. In 1942 Bauer and Engleman⁵⁰ first reported it in the American literature with their series of 6 cases. In 1944 Lever and Crawford⁵¹ followed with a report of 2 cases, the second of which (the only case so far reported in a female) left them in doubt regarding its proper classification.

Although in many cases the clinical picture is one of average chronic polyarticular arthritis associated with mild and fleeting inflammation of the mucosa of the eye and genitals, when Reiter's disease is in full bloom a low-grade fever is present,

lesions of the buccal mucosa and of the epidermis occur, its mild conjunctivitis becomes an extensive iritis and keratitis, its arthritis settles in several joints and is of deforming proportions, sometimes ending in ankylosis, and its urologic manifestations extend to widespread superficial ulceration of the glans penis and even the urethral and bladder mucosa, causing discharge, pyuria and protracted severe cystitis. Yet the disease is completely devoid of any bacterial basis demonstrable by smear, culture, skin test and complement-fixation test or dark-field examination. Two patients whose cases were reported were attached to the same construction battalion, and their duties led to rather close association over periods of eight and nine months, respectively, prior to the beginning of the illness. The disease strongly suggests an infectious cause. Further study may prove that it falls into the ever-growing group of virus diseases. Idiopathic blennorrhoeal arthritis is suggested to give a fairly descriptive terminology to this little-known disease and to escape the use of a proper name.⁴⁹

In 1945 Rosenblum⁵² reported 10 cases of Reiter's syndrome in personnel of the United States Navy, of which 5 arose in the South Pacific and 5 in the United States. One patient had a widespread, acute skin eruption resembling erythema multiforme.⁵³ I recently treated a severe case at the United States Public Health Hospital in Brighton. The patient, a young man who had conjunctivitis, urethritis and arthritis, presented lesions in the axillary and genitocrural regions consisting of small bullae. Vesicles and bullae appeared on the palms and soles, and the eruption later became a dermatitis exfoliativa with complete loss of hair. The skin and hair became normal in several months, with complete recovery, and there was no limitation of joint motion.

METABOLISM

Numerous articles describing cutaneous manifestations of nutritional disturbances have recently appeared. In 1888 Gee published a classic description of idiopathic steatorrhea. In this affliction skin lesions are frequent and diversified, they may be pigmented patches, psoriasisiform plaques, eczematous areas or pustular dermatitides. The combination of skin lesions, infantilism, anemia, osteomalacia, tetany, dilatation of the colon and fatty stools may be found in a patient suffering from celiac disease.⁵⁴

There are four centuries intervening between the scurvy of the days of the Crusaders and the beginning of our present-day knowledge of the subject. Impetiginous eruptions were described nearly two hundred years ago, in 1763 Cutaneous avitaminosis in children has been reviewed by Ormsby et al.,⁵⁵ who state that the lesions due to vitamin A deficiency are similar to those found in adults, except for lichen spinulosus, which is found exclusively in children and

is characterized by minute papules situated over the pilosebaceous follicles, each with a projecting horny spinule. Pellagra is usually less marked in children. With all the literature on avitaminosis one wonders why more skin diseases from nutritional deficiencies were not reported from concentration camps. Parasitic diseases were frequent, but pictures of starved prisoners showed no evidence of cutaneous manifestations. Some cases of pellagra, however, were reported. Among war prisoners in Java and Sumatra, the localization of true pellagra pigmentation was usually on the back of the hands and the feet and on the dorsal skin, sometimes the hair turned from spotless black to gray in three months.⁵⁶

Chavarria et al.⁵⁷ report that hair disturbances have been noted in children, especially in the severe forms of vitamin A deficiencies, pellagra, riboflavin deficiency (cheilosis), nutritional edema, beriberi and the mixed forms of these general groups. They exhibit characteristic, associated changes in the hair, including both loss—diffuse or especially pronounced in the frontal area—and depigmentation. Biotin is thought but not proved to accelerate over other therapies the return to normal growth and pigmentation of the hair.⁵⁷ In the Medical Survey of Nutrition in Newfoundland note was made of a form of change in the hair—namely, a dry, lack-luster hair, so-called “staring hair.”⁵⁸

The subject of the relation between the so-called “rosacea keratitis” and cutaneous rosacea has been debated a bit acrimoniously. A riboflavinosis due to the vitamin B₂ deficiency is well known. There is considerable disagreement among the ophthalmologists themselves and the dermatologists regarding ocular disturbances. This was stimulated by a paper published in 1939 on the effect of experimental riboflavin deficiency on corneal vascularization in rats.⁵⁹ In 1940, after observing the relief of excessive corneal vascularization in 36 patients, although only 9 showed some type of cutaneous disturbance, Johnson and Eckardt⁶⁰ made a diagnosis of rosacea keratitis. In June, 1940, Sydenstricker et al.⁶¹ reported a careful survey of 45 patients in whom they found this same type of corneal vascularization, originating at the limbic plexus and extending centripetally, originally described by Bessey and Wolbach.⁵⁹ Sydenstricker labeled this eye disease dietary keratitis, but in November, 1940, Johnson⁶² claimed rosacea keratitis to be identical with dietary keratitis. He reiterated this a year later⁶³ but admitted that rosacea is a poor term since the condition is not caused by acne rosacea. Subsequently, two papers, one by an ophthalmologist (Fish⁶⁴) and another by a dermatologist (Wise⁶⁵), and later a statement by Johnson⁶⁶ that the appearance of keratitis with acne rosacea is a coincidence, fairly well established the fact that the term “rosacea keratitis” is confusing and may have disastrous results. Ocular rosacea follows acne rosacea, and both are manifestations of the same disease and are

not due to riboflavin deficiency. Ocular rosacea is due to staphylococcal infection and must be treated by local antiseptic applications. I have repeatedly seen patients with severe ocular rosacea who did not improve until the local therapy was applied to the skin.²⁶

Metabolic diseases of the liver are manifested by cutaneous discolorations ranging from jaundice to the irregular, yellow-brown pigmentation of the lower legs and yellowish, wedge-shaped conjunctival thickenings near the cornea. In many liver diseases, multiple functions being affected, more than one alteration in the appearance of the skin is observed.

Brunsting and Mason⁶⁷ report that bullous eruptions simulating epidermolysis bullosa, in which the exposed surfaces are sensitive to light, occur in association with porphyria and may represent the presenting symptoms of the disorder. Porphyria is recognized as a rare familial, metabolic fault in which abnormal kinds and amounts of porphyrins, especially uroporphyrin, are excreted in the urine and feces. Granted that there is a certain correlation between bullous eruptions, photosensitivity and porphyria in animals and in man, it is not proved that the production of the bullae on the exposed surfaces is due to the photodynamic action of porphyrins in the skin. Cutaneous signs of epidermolysis bullosa, melanosis and hypertrichosis were present in a case of porphyria, presumably of the tardive congenital type, occurring in a fifty-eight-year-old woman who had hepatic dysfunction and a history of alcoholism.⁶⁷

The most striking and familiar skin affection associated with liver disease is jaundice. Pruritus is often associated with jaundice. It may be present without visible jaundice and may be the first indication of liver disease or, conversely, need not be present even though the icterus is marked. Biliary disease has also been reported to be the cause of 48 per cent of 200 cases of urticaria studied by Menagh,⁶⁸ who states that treatment of the biliary disease cured the urticaria in 60 per cent of cases.

A frequent finding in patients with liver disease is that of angiomas (telangiectasia or “spider angiomas”) appearing on the face, neck, upper portion of the chest, shoulders and arms. Bean⁶⁹ asserts that there is an increase in the estrogen content of the blood, owing to inability of the liver to detoxify or otherwise cause an inert estrogen to be formed. Spider angiomas in the acute stage of infectious hepatitis have occasionally been described.^{70, 71} In a clinical study of Navy patients at the Rockefeller Hospital, approximately 30 per cent developed spider angiomas during the acute stage of the disease.⁷² New spider angiomas usually signified a poor prognosis when they developed after the acute stage of hepatitis.⁷³

The vascular “spider” (naevus araneus, spider telangiectasia, spider angioma, stellate naevus and so forth) is a bright-red lesion characterized by a

central point from which fine, hairlike branches radiate for a distance of about 1 cm. Vascular spiders are seen in healthy persons, alcoholic patients, pregnant women and patients with liver disease and in avitaminosis. There is a hereditary tendency in which the lesions are found scattered over the skin and in the mucous membranes — that is, hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome).

Williams and Snell⁷⁴ have suggested that the tendency to vascular spiders is transmitted as a dominant trait in some persons and as a recessive trait in others. The characteristic appears to be dominant in hereditary hemorrhagic telangiectasia, whereas it is probably recessive when there is no definite familial tendency. Vascular spiders frequently antedate the symptoms and signs of hepatic disease by as long as fifteen to twenty years. Patek et al.⁷⁵ reported them in 48 of 63 patients with hepatic cirrhosis. In a more extensive study of 368 cases of cirrhosis, Ratnoff and Patek⁷⁶ described vascular spiders in 15 per cent and telangiectasia in 17 per cent. The vascular spiders associated with pregnancy appear between the second and fifth months, usually increase in size and number until nearly term and may disappear abruptly a few days after delivery. Another group includes persons who are known to have or are suspected of having vitamin-deficiency diseases.

Palmar erythema may be hereditary or acquired, the latter being most frequently associated with liver disease, but occasionally with pregnancy and possibly with vitamin deficiencies. Ratnoff and Patek⁷⁶ reported this condition in 16 of 486 patients with cirrhosis of the liver, with a review of 20 cases of erythema palmare hereditarium, 9 presented by Walsh and Becker⁷⁷ and 11 collected from the literature. In 4 of their cases the condition appeared during pregnancy and was associated with the development of lesions similar to naevus araneus on the arms, face, neck and upper part of the chest. The complete clinical picture has not previously been described. Capillary studies usually show a dilatation of the venous side of the capillary loops and the superficial venous plexus.⁷⁷

When estrogens were injected into patients with liver disease, angiomas appeared. Palmar erythema, especially thenar and hypothenar, was observed. Many chronic alcoholic patients show hypertrophy of the breasts and partial loss of pubic and axillary hair.

The skin manifestation due to faulty prothrombin and fibrinogen production consists of purpuric lesions and bleeding from the mucosal surfaces, especially the nose. The syndrome of pernicious anemia may result from inability of the liver to store the EMF as a result of disease. The skin manifestations may be pallor, glossitis, icterus and graying of the hair. The liver converts provitamin A to vitamin A, which it stores. In severe chronic disease of the liver,

vitamin A deficiency results, with xerophthalmia, a dry, harsh skin, follicular keratosis and acneiform eruptions. Yellow discoloration of the skin due to carotenemia may be secondary to liver diseases.

A skin disease and liver disease may coexist with neither the primary source in many cases, as in hemochromatosis, in which there is bronzing of the skin, loss of hair, a pigment cirrhosis of the liver and diabetes. At the same time, liver disease may occur secondary to skin disease. Miyake et al.⁷⁸ have shown that there is a so-called "G substance" in the skin of animals with a dermatosis that, when inoculated into rabbits, causes pathologic changes (chiefly cloudy swelling) in the liver, kidney and testis. Iwama⁷⁹ noted hepatic and renal insufficiency in cases of exfoliative erythroderma. One of his studies seems to offer evidence in favor of the liver as the cause of skin reactions. He concludes that there is a close relation between liver and skin disease.⁸⁰

Altered metabolism of the liver may result in the formation of xanthomas. When one observes a yellow lesion or eruption on the skin, Melicow's⁸¹ classification provides excellent data for a differential diagnosis. He states that xanthoma as a general term is inadequate and that the prefix "xanthic," which accurately characterizes the underlying condition, is more logical in most cases. According to his classification, the "pseudoxanthomas" or preferably the "xanthic granulomas" are manifestations of the reticuloendothelial response to destructive processes resulting in the accumulation of lipids and blood and are found in chronic inflammatory foci, neoplasm, possible selective response to an unknown irritant and when a metabolic disturbance is not demonstrable, such as xanthic granuloma palpebrarum (xanthelasma) or multiple xanthic granulomas, and possible response to repeated pounding, as in large arteries when cardiac hypertrophy and hypertension are present.⁸² The xanthomatoses or preferably, the "xanthic lipidoses" are primary or secondary. Xanthic neoplasms included "xanthoma" or xanthic fibroma and xanthocarcinoma. Lesions simulating xanthic entities because of similarity in color comprise pseudoxanthoma elasticum, traumatic fat necrosis of breast and so forth, fibrohemangioma, hemorrhagic buritis, hemorrhage in a lipoma, myxoma or fibromyxoma and melanotic tumors.

The classification of xanthomas has been confusing, probably owing to deficient knowledge of the normal physicochemistry of lipid metabolism. Various hormones in the pituitary and thyroid glands, the pancreas and the sex glands are closely linked with lipid metabolism. Disturbances of utilization of or deficiencies of various vitamins are also factors. Hypercholesterolemia and hyperlipemia may be seen in myxedema with lesions on the skin.

The exact etiology of the xanthomas is unknown, not all are associated with a hyperlipemia, and they may occur without liver disease. Montgomery,⁸³

however, in a series of cases noted that cutaneous xanthomas (xanthoma tuberosum, xanthoma disseminatum and xanthelasma) are not infrequently seen in association with liver disease, especially in obstructive jaundice. There is usually a hyperlipemia with an increase in lecithin. Palmar lesions are frequent, often in association with lesions of the mucous membrane. Xanthomas often involute as the liver disease improves.

Eusterman and Montgomery⁸⁴ report the case of a woman of forty-eight who came to the Mayo Clinic in May, 1941, complaining of severe, refractory generalized intense pruritus, continuous aching pain and hyperesthesia, especially in both extremities, cutaneous yellow nodules, gastrointestinal disturbances, loss of weight and strength, yellowing discoloration of the skin and severe physical and nervous exhaustion. They stress the fact that cutaneous xanthomas and hyperlipemia occasionally occur in association with primary disease of the liver (so-called "xanthomatous biliary cirrhosis") and in association with hepatic disease that is secondary to obstruction of the common bile duct, especially as the result of postoperative stricture. In cases in which the hepatic disease is primary, the prognosis is generally unfavorable. It is more favorable in cases in which the underlying pathologic process is due to obstruction of the common bile duct.

Combes and Behrman⁸⁵ discuss xanthoma diabetorum and present a review of 181 cases from the literature. They suggest the more appropriate title "xanthoma eruptivum." The essential clinical features of the disease consist of the sudden appearance of multiple reddish-brown papules and nodules vaguely resembling erythema multiforme at their onset. The distribution is extensive, and the sites affected in particular are the extremities, the trunk and the mucosae. The lesions start as lentil-sized translucent nodules, sometimes with a small central blister. The diseases reported as extracellular cholesterosis and pseudodiabetic xanthoma are in all probability variants of xanthoma eruptivum.

To add to the confusion, a new entity—eosinophilic granuloma—has caught the interest of clinicians. In 1923 the histogenesis of eosinophilic granuloma was described as an unknown entity. The lesions have a dull erythematous appearance. They appear first as macules and develop into nodules or patches of firm elastic consistence varying in size from a millimeter to several centimeters. The accompanying blood eosinophil count ranges from 2 to 55 per cent, with an average of 20 per cent, lasting from two months to fifteen years. The name implies that there is an infiltration of polynuclear and mononuclear eosinophils in the dermis, which may extend into the subcutaneous tissue.⁸⁶

Johnson and Zonderman⁸⁷ report a case involving the frontal bone, with recovery following surgery and x-ray therapy. Jaffe and Lichtenstein⁸⁸ define eosinophilic granuloma as a "condition affecting

one, several or many bones, but apparently limited to the skeleton, and representing the mildest clinical expression of the peculiar inflammatory histiocytosis also underlying Letterer-Siwe disease and Schüller-Christian disease." Green and Farber,⁸⁹ Mallory,⁹⁰ Jaffe and Lichtenstein⁸⁸ and others have shown that the underlying lesion of this disease is related to the lesions of Schüller-Christian's disease and those of Letterer-Siwe's disease, which represents the gravest (eosinophilic granuloma representing the mildest) expression of the same basic pathologic process, which appears to have a predilection for the hemopoietic system. When this "peculiar inflammatory histiocytosis" manifests itself in infancy in its severe and often fatal form—characterized clinically by fever, purpuric skin rash, rapidly progressive hypochromic anemia, enlargement of the spleen, liver and lymph nodes and destructive bone lesions—it is classified as Letterer-Siwe's disease (aleukemic reticulosis, nonlipoidal histiocytosis). In its more chronic and less severe form, occurring in childhood and early adult life, after the lesions of the soft tissues and the bones have undergone lipogranulomatous changes, and especially—although not characteristically—when the Christian triad of symptoms (calvarial defects, exophthalmos and diabetes insipidus) has developed, the disease is labeled Schüller-Christian's disease (lipogranulomatosis). Roentgenographically the lesions appear as radiolucent areas varying in size. In the skull they tend to be round and sharply defined and have a punched-out appearance.

Nanta and Gadrat were the first to use the full term "eosinophilic granuloma of the skin" in 1937. This term was applied to bone by Finzi in 1939. The syphiloid of cats was described as "la syphiloïde du chat (granulome eosinophilique)" by Henry and Bory in 1937. On the basis that Nanta and Gadrat have priority, the characteristics in their case should serve as the type for eosinophilic granuloma of the skin. The earlier reports of the disease indicate that the authors arrived rather promptly at the conclusion that it was not a clinical or etiologic entity. Therefore, the term can be used with the utmost latitude in any dermatosis with extreme eosinophilia in the tissues. In any event, attention should be focused on newer factors in the life of the population that might bear an influence on its tissue, especially the hemopoietic ones. The sulfonamides, barbiturates, aminopyrin and ethyl lead must be thought of when the clinical history is being elicited. In Weidman's⁴¹ cases only two opportunities were supplied for testing for the presence of fat in the skin. Lever,⁹¹ alone, raised this subject, he found new lipid-laden histiocytes and foam cells in his sections. In Weidman's sections there was no evidence of such disintegration.

Troxler and Niemetz⁹² report a case of generalized xanthomatosis with involvement of bone, lungs and cerebrum. The unusual complication of bilateral

spontaneous pneumothorax occurred in this case. In the discussion they mention Hand-Schüller-Christian's disease as being considered as craniohypophyseal localization of lipid granulomatosis. They quote Green and Farber⁹¹ in concluding that eosinophilic or solitary granuloma of the bone is one form of generalized xanthomatosis and not a new disease entity. These authors also describe Letterer-Siwe's disease or reticuloendotheliosis as the same pathologic process seen in Hand-Schüller-Christian's disease. Wherever there is reticuloendothelium there can be lipid granulomatosis. Thus, the clinical symptoms produced depend on the tissues involved and the degree of involvement.

Several interesting papers reporting eosinophilic granuloma with cutaneous manifestations have appeared in the dermatologic literature.⁹²⁻⁹⁴ Just as I had decided on the cutaneous picture of eosinophilic granuloma, I saw a case of Thannhauser's presenting yellow, xanthomatous plaques on the eyelids and a yellowish, saber-blade type of patch extending from the hairy margin to the vertex of the scalp, with multiple small, dark-brown macules on the extremities, with symptoms of cerebral involvement and with a positive biopsy from the femur.

Some believe that eosinophilic granuloma is merely a late stage of a xanthomatous process. Others regard the lipid factor as a secondary development due to the infiltration of the lipid material into the granulomatous tissue. Apparently there are several symptom complexes with individual cases showing characteristics of more than one group. These syndromes include xanthomatosis of the skin and mucous membranes, Hand-Schüller-Christian disease, Niemann-Pick disease, Tay-Sachs disease and Gaucher's disease. A hypercholesteremia may or may not be present. Xanthomatous nodules and plaques may appear in almost any tissue, occasionally with enlargement of the spleen, liver and lymph nodes. Therefore, when a physician sees a cutaneous yellow lesion he should consider it a cutaneous manifestation of a general disturbance until he proves otherwise. Xanthomas secondary to general pathologic conditions such as diabetes mellitus and jaundice tend to disappear with proper systemic therapy. Skin lesions, however, may be independent of other disease.

Niemann-Pick⁹⁵ disease, or acute idiopathic lipidosis, is a rare congenital familial disorder of lipid metabolism in which the blood and tissues become overloaded with lipids, chiefly the phosphatide lecithin. The disorder begins in infancy, usually in the first six months of life and nearly always before the age of one year. Pfändler⁹⁶ reviewed observations on 14 members of a family in which 2 brothers died with Niemann-Pick disease at the ages of twenty-nine and thirty-three years, respectively. These cases demonstrate that this disease is exclusively a disease of infants and young chil-

A genealogical tree of the family illustrates diagrammatically the various forms in which Niemann-Pick disease became manifest. Pfändler regards the latent forms as possibly more frequent than is generally believed.

Gaucher's disease, the second related disease, is a rare familial constitutional disorder of metabolism. It was first described by Gaucher⁹⁷ in 1882. The two types — the chronic and the rare acute form — are characterized pathologically by an enormously hypertrophied spleen and an enlarged liver, each of which shows on microscopical examination an infiltration of cells peculiar to the condition. These distinctive cells vary in diameter from 20 to 40 microns, stain palely with eosin and are usually oval or polygonal. The typical eruption of Gaucher's disease is a brownish-yellow pigmentation or bronzing of the skin, more pronounced and of a deeper hue on the face, neck, forearms and hands.⁹⁸⁻¹⁰⁰ The other common lesions of the skin are of the hemorrhagic type — that is, petechiae, ecchymoses and hemorrhagic furuncles.^{101, 102} A diagnosis of Gaucher's disease is suggested by an enormous abdomen, bronzing of the skin and a hemorrhagic diathesis. The presence of Gaucher's cells in the biopsy material from a peripheral lymph node or a splenic puncture is positive proof of the diagnosis.¹⁰³

Acute pancreatitis is accompanied by a pallor, cyanosis or lividity of the face and a cold clammy skin. Intestinal infestations may announce their presence by pruritic symptoms and lesions varying from a perianal eczema to the giant wheal. Persistent diarrhea with dermatitis and some mental change complete the syndrome of pellagra.

Blood

Osler was one of the first to recognize the syndrome called polycythemia vera, splenomegaly, cyanosis (erythrosis) and plethora.¹⁰⁴ Strickler¹⁰⁵ states that there are two frequent cutaneous manifestations of polycythemia vera: a purplish redness of the gums due to a highly reduced oxyhemoglobin content of the blood and a papular, pruritic, urticarial eruption with surmounting vesicles or pustules occurring in crops, which later become bloody crusts. This has been called *acne urticata* polycythemia.

Klauder¹⁰⁶ previously described this entity in a patient who had typical signs and symptoms consisting of headache, hypertension, albuminuria, hepatosplenomegaly, vasomotor instability, flushing, dermatographism, a high blood uric acid and occasional ecchymosis. Marsh¹⁰⁷ distinguishes between the cyanosis seen in anoxic diseases and the erythrosis present in this entity, in which there is often an increased oxygen content. Brown and Griffin¹⁰⁸ believe that cutaneous lesions may be due to multiple thrombi and conclude that the erythrosis is due to peripheral vessel engorgement.

Anemia has various skin manifestations — the wax, waxy, delicate skin of the victim of pernicious

anemia, the green-yellow tint of the sufferer from hypochromic anemia and the smoothness and shiny appearance of the tongue seen in dysphagic old women with the Plummer-Vinson syndrome¹⁰⁹ Spoon nails are also noted in this disease¹¹⁰

Ulcers of the legs are observed in sickle-cell anemia, exclusively in Negroes^{111, 112}

Infectious lymphadenosis may present a roseolar eruption resembling syphilis, and an accompanying positive serologic reaction may deceive the unwary physician Dameshek and Grassi¹¹³ reported the case of a young woman with severe purpura hemorrhagica accompanied by generalized lymphadenopathy and a marked lymphocytosis Although the clinical picture resembled that of acute lymphatic leukemia, the character of the lymphocytes suggested infectious mononucleosis, this was confirmed by a strongly positive heterophil-antibody agglutination When the bleeding became uncontrollable, splenectomy was performed and resulted in prompt recovery

Urticaria may be present in acute infectious lymphocytosis¹¹⁴ Eosinophilia may be found in conjunction with diseases of the skin Kirk¹¹⁵ divides the causes of eosinophilia into five classes intestinal parasites — nematodes and some cystodes, blood diseases — eosinophilic leukemia and Hodgkin's disease, skin diseases — dermatitis herpetiformis and pemphigus, allergic diseases — asthma, eczema and hay fever, and miscellaneous diseases — periarteritis nodosa, trichinosis and Loeffler's syndrome and those occurring after the ingestion of raw liver A significant rise in the eosinophils is present in urticaria, the neurodermatoses, pemphigus, erythema multiforme bullosum, dermatitis herpetiformis, hydroa, herpes iris, herpes gestationes and rarely in psoriasis¹¹⁶

The eosinophil has been called a histamine scavenger I have seen a 97 per cent eosinophil count with a white-cell count of over 65,000 in a case of generalized dermatitis from mercury The blood became normal with clearing of the rash Perhaps further study of eosinophilia will reveal the etiologic factor in some bullous diseases

Purpura has been reported as resulting from many different factors — heredity, avitaminosis, allergy, anaphylaxis, infection, drugs and physical anomalies As knowledge of the relation of drugs, infection and certain other conditions to thrombocytopenic purpura increases, the disease is less often described as idiopathic Infection as an exciting cause of purpura is mentioned in most discussions of the etiology of thrombocytopenia The etiologic importance of localized infection in the throat has been emphasized by many writers Thrombocytopenic purpura following angina was considered sufficiently rare to warrant report of a fatal case¹¹⁶ Frey¹¹⁷ and Berg¹¹⁷ reported the first case in which the initiation of a vaccine followed by

angioneurotic edema involving parts of the body far from the site of the injection Hampton¹¹⁸ states that food allergy caused 2 cases of purpura of the Henoch type

Rucks and Hobson¹¹⁹ reiterate that purpura fulminans is with few exceptions found in children owing to a fulminating blood-stream infection They have reviewed 101 cases

It is stated that purpura following the use of drugs such as arsenic, sulfonamides, coal-tar derivatives and gold is fairly frequent¹²⁰⁻¹²² Several excellent reviews on purpura have recently been published¹²³⁻¹²⁷

In discussing a rare fatal case of Henoch-Schönlein's purpura, Moore¹²⁸ states that fibrosis of the liver, seen in this case, is not found in lupus erythematosus or periarteritis nodosa, which others considered in differential diagnoses

The detection of the causative factor of a purpuric eruption necessitates careful history taking, physical examination and laboratory studies Very few cases can be diagnosed from observation, and the services of an expert hematologist are usually required

Although in the experience of some clinicians leukemia cutis is rare,¹²⁹ in the practice of the dermatologist it is frequent enough to keep the possibility of its occurrence ever present in his mind A persistent pruritus always demands a thorough blood study in the young or the old. An acute ulcerative stomatitis may be the precursor of monocytic leukemia, and an acute exfoliating dermatitis may precede by months a change in the blood picture I have seen so many varied types of eruption accompanying the leukemias that I hesitate to name any single eruption as being specific, for even in the tumor stage the lymphomas may all resemble one another histologically and repeated biopsies are often necessary for the final diagnosis The nonspecific lesions may be wheals, extravasation of the blood, papules, vesicles (single or grouped), bullae or ulcerations Herpes zoster is frequently associated with the lymphatic group Within two months I saw a patient with a generalized herpes zoster and another with an exanthema indistinguishable from varicella. Specific lesions due to infiltration of the leukemic process in the skin are those producing erythroderma, nodules and tumors, the last may break down into ulcerations Nodules appear most frequently on the skin Many excellent reviews have been published on the oral and cutaneous manifestations of the leukemias¹³⁰⁻¹⁴⁶

Jackson and Parker¹⁴⁶ state that the skin lesions of Hodgkin's granuloma are often encountered Marked excoriations due to severe pruritus of the skin are perhaps the most frequent lesions Generalized or, more rarely, localized pigmentation occurs aside from that due to radiation therapy Herpes zoster, not infrequently of a hemorrhagic type and often leaving behind it an indurated scar, is not unusual The more specific lesions are generally

nodular or ulcerated and may exist for a long time prior to unequivocal evidence of the disease elsewhere.¹⁴ Generalized exfoliating dermatitis has been reported, Jackson and Parker¹⁷ saw 1 patient with this complication. In the past year I have treated 2 patients with a generalized dermatitis due to Hodgkin's disease.

The clinician should bear in mind that any chronic skin disease, whether it starts as a simple itchy eruption, such as parapsoriasis or psoriasis, or a vesicular eruption, such as chronic eczema, may eventually terminate as a fatal lymphoma. Hodgkin's disease should always be suspected in a persistent dermatitis exfoliativa, even if there is no visible adenopathy. I have seen more cases in the last few years than in all my previous years of practice. A well known hematologist remarked that the sulfonamides may be a factor, but I have failed to find a history of the ingestion of this drug except in the case of erythroderma suspected of being Hodgkin's disease. Other authors have reported eruptions varying from ichthyosis to ulceration.¹⁴⁻¹⁸

(To be concluded)

EDITH E. PARRIS, Assistant Editor

CASE 33501

PRESENTATION OF CASE

A sixty-seven-year-old man entered the hospital with the chief complaint of food sticking in his throat.

For four months he had had difficulty swallowing solid food. If he swallowed a large particle, it stuck and produced a burning sensation in the lower sub-sternal region, and no more food could pass for a while. Induced vomiting relieved the block. Liquids and soft solids were easily swallowed. There had been no weight loss, pain, cough or hematemesis. He had been slightly hoarse for three weeks.

X-ray studies and esophagoscopy at another hospital had demonstrated a lesion of the lower esophagus, which was not further described.

Physical examination disclosed a Grade II apical systolic murmur and a slightly enlarged prostate.

The temperature was 98°F, the pulse 60, and the respirations 17. The blood pressure was 160 systolic, 70 diastolic.

Examination of the blood revealed a hemoglobin of 15.1 gm and a white-cell count of 8000. The urine was normal, with a specific gravity of 1.027. The total protein was 6.3 gm and the nonprotein nitrogen 29 mg per 100 cc. An electrocardiogram showed changes consistent with coronary-heart disease.

X-ray examination demonstrated an essentially normal chest. A gastrointestinal series showed a 2-cm area of narrowing in the distal portion of the esophagus. No ulceration was seen. No tumor mass was visible. There was herniation of a portion of the stomach through the diaphragm. The films were otherwise negative.

An esophagoscopy was not performed. On the eighth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD B. BENEDICT. Difficulty in swallowing is a very serious symptom and may be produced in a number of conditions, including benign and malignant tumor, benign stricture, cardiospasm, peptic ulcer of the esophagus, esophagitis, chemical burn and foreign body.

At the age of sixty-seven years, with a four-month history of dysphagia beginning with difficulty in swallowing solid food, the presumptive diagnosis is carcinoma of the esophagus until proved otherwise. The fact that food stuck and produced a burning sensation in the lower sub-sternal region indicates that the lesion was in the lower esophagus, and the burning sensation points a little more toward an inflammatory process such as ulcer or esophagitis with benign stricture than to a tumor or to cardiospasm. The relief of the obstruction by induced vomiting does not help very much in the differential diagnosis. That liquids and soft solids were easily swallowed merely indicates that the obstruction was not complete and does not aid very much in the differentiation of a benign stricture from a carcinoma. One would expect, however, that an annular carcinoma of four months' duration would have produced some difficulty in swallowing soft solids and would probably have resulted in some loss of weight. The absence of pain is definitely against a diagnosis of peptic ulcer of the esophagus and somewhat against that of acute esophagitis. Sub-sternal burning, however, is closely akin to pain. A cough in esophageal disease is usually secondary to rather complete esophageal obstruction with

spillage of food material into the trachea. This may occur in advanced cardiospasm or the late stages of carcinoma. There is little in the history to suggest cardiospasm, which is usually a disease of younger persons and occurs intermittently, frequently with emotional factors prominent in precipitating the attacks. The absence of hematemesis is not particularly helpful, because even in the presence of large ulcers or cancers of the esophagus, bleeding may not be a prominent symptom, and what bleeding does occur may be in the form of melena.

The hoarseness of three weeks' duration suggests the possibility of a malignant lesion with pressure on the recurrent laryngeal nerve and paralysis of a vocal cord. The hoarseness, however, may have been an incidental finding and not related to the esophageal disease, but due to a laryngitis.

There is nothing in the history to suggest a chemical burn such as the ingestion of lye, nor is there any history of foreign body.

Physical examination and laboratory studies are not particularly helpful, but a normal hemoglobin suggests the absence of cancer and the absence of a bleeding lesion.

We are told by the radiologist that there is a hiatus hernia and 2-cm. area of narrowing in the distal esophagus, with no visible ulceration or tumor mass.

The differential diagnosis from the above discussion seems to boil down to a carcinoma of the distal esophagus and a benign stricture with or without peptic ulceration. The fact that no ulceration was seen does not mean that none was present, for small ulcers of the esophagus are notoriously hard to demonstrate by the x-ray. The absence of a tumor mass is somewhat against the diagnosis of carcinoma. We are not told whether the area of narrowing is irregular or whether the margins of it are smooth. Obviously, a smooth narrowing would be more suggestive of a benign stricture, whereas a nodular narrowing would suggest cancer. Smooth narrowings, however, should always be viewed with some suspicion, since there may be a relatively smooth annular carcinoma simulating a benign stricture.

On the whole, I vote for benign stricture of the lower end of the esophagus associated with esophagitis for the following reasons: burning sensation in the lower substernal region, no weight loss, normal hemoglobin, no evidence of nodularity by x-ray examination and the presence of a hiatus hernia as described on x-ray study.

It has been my experience that benign strictures of the esophagus quite frequently occur in association with hiatus hernia, duodenal ulcer or esophageal ulcer. In a study of 44 cases I found that the disease was relatively infrequent in women, and that it occurred usually in men over fifty years old. In the series reported the benign stricture was associated with hiatus hernia in 17 cases, with duodenal

ulcer in 15 and with esophageal ulcer in 8.* All the patients had some esophagitis.

In the case presented herewith no esophagoscopy was performed, presumably because the surgeon planned to do a resection of the lower end of the esophagus, regardless of whether he was dealing with a benign stricture or with a carcinoma. This method of treating a benign stricture of the lower end of the esophagus is a debatable point, since the results of esophagoscopy and bouginage, a previously swallowed thread being used as a guide, are usually satisfactory. In my opinion esophagoscopy should be done in all these cases, and adequate biopsy obtained from the lumen of the stricture, to make absolutely positive that one is not dealing with carcinoma. Bougies may then be passed at regular intervals, and a major operation thus avoided. It must be remembered that patients with esophagitis and benign stricture may have a normal acidity, and that the usual operation of esophageal resection with esophagogastric anastomosis leaves the lower end of the esophagus even more vulnerable than before to the action of the acid gastric juice, thus leading to the possibility of further esophagitis with or without esophageal ulcer. The time for major surgery in a patient of this sort, sixty-seven years old, is, it seems to me, after conservative measures have failed.

Dr. Robbins, will you please help us with the x-ray interpretations?

DR. LAURENCE L. ROBBINS: Although I did not fluoroscope the patient, the films show a small hiatus hernia and approximately 2 cm. above the cardia of the stomach there appears to be a crater about 1 cm. in diameter. There is no evidence of a shelf, and no mass is seen either extrinsically or protruding into the lumen.

The remainder of the stomach and the chest show no evidence of tumor.

DR. BENEDICT: Dr. Robbins believes that there is probably an esophageal ulcer. The radiologist who did the fluoroscopy saw no ulceration. Naturally, it is impossible to be sure. My diagnoses are hiatus hernia, esophagitis, benign stricture of the esophagus and question of esophageal ulcer.

DR. RICHARD H. SWEET: One of the principal reasons for operating on this man was the fact that an esophagoscopy had been performed at another hospital by a competent endoscopist and that a biopsy specimen obtained at that examination had been reported as epidermoid carcinoma by the pathologist. Obviously, the history was not that of carcinoma because of its long duration. Also, the patient was actually able to swallow considerable food at the time we saw him even though he had had his trouble for a long time.

An exploration of the chest was therefore carried out, and at operation, although it was not ab-

* Benedict, E. B. Benign stricture of esophagus. *Gastroenterology* 6: 328, 1946.

solutely certain that we were dealing with a benign lesion, it seemed more than likely that it was an inflammatory stricture with ulceration rather than carcinoma, although a small carcinoma superimposed on an ulceration in that region could exist without my being able to determine its presence by palpation and inspection alone. I have actually had that experience in just such a case.

This brings up an important point, which I believe should be mentioned lesions of this sort, in my opinion, should be regarded with as much suspicion as the prepyloric ulcers of the stomach because as experience is accumulated with them, I am willing to predict that there will appear to be a correlation between the pre-existence of such a lesion and some cases of carcinoma, of about the same magnitude as that with prepyloric ulcer.

I therefore proceeded with a resection and an esophagogastric anastomosis.

CLINICAL DIAGNOSIS

Carcinoma of esophagus, benign stricture with ulceration?

DR. BENEDICT'S DIAGNOSES

Benign stricture of esophagus, with (?) ulcer
Esophagitis
Hiatus hernia

ANATOMICAL DIAGNOSES

Peptic ulcer of esophagus
Acute and chronic esophagitis

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN The specimen received in the laboratory showed a shallow ulcer 2 cm. in diameter whose margins were irregular but well defined and not indurated. Microscopically, the base of the ulcer was covered with a fibrinoid membrane characteristic of peptic ulceration. There was no evidence of carcinoma. The surrounding esophageal mucosa and muscularis were moderately inflamed.

DR. SWEET The patient made an exceedingly rapid and favorable convalescence. At the time he left the hospital he was eating a liberal solid diet with much more comfort than he had for years.

CASE 33502

PRESENTATION OF CASE

First admission. A sixty-nine-year-old physician was admitted to the hospital complaining of slowing of the urinary stream and nocturia.

For several years the patient had suffered from increasingly severe nocturia, frequency and difficulty in starting the urinary stream. He had had diabetes for several years and was satisfactorily

controlled on 8 units of protamine-zinc insulin daily.

Physical examination revealed a healthy-appearing, unusually well preserved man. The heart was of normal size, and a soft systolic murmur was heard at the apex. The abdomen was normal. Rectal examination disclosed a smooth, symmetrically enlarged prostate.

The temperature, pulse and respirations were normal, the blood pressure was 165 systolic, 90 diastolic.

Examination of the blood revealed a hemoglobin of 13.8 gm. and a white-cell count of 6100. The urine had a specific gravity of 1.020 and gave a + test for albumin and a negative test for sugar. The urinary sediment contained 10 red cells, 150 white cells and numerous bacteria per high-power field. The nonprotein nitrogen of the blood was 122 mg. per 100 cc. A blood Hinton test was negative.

X-ray studies showed normal kidney outlines, the left kidney being somewhat low. The ureters were not dilated. No unusual soft-tissue mass was present. A large amount of mottled calcification was seen in the region of the prostate. The walls of the pelvic vessels were calcified.

On the fourth hospital day cystoscopy showed marked trabeculation of the bladder but was otherwise not remarkable. A perineal prostatectomy with removal of 20 gm. of tissue was performed. Pathological examination revealed hyperplasia and chronic prostatitis.

Recovery was uneventful, and the patient was discharged on the nineteenth hospital day.

Second admission (six months later). The patient had felt well for the first three months following discharge, but then noted indefinite suprapubic discomfort and pain. The pain gradually became severer and seemed to be localized in the right lower quadrant. In addition he had a slight afternoon fever. He was nauseated once, but there was no vomiting or change in bowel habit.

During the week prior to admission penicillin was administered without much effect. On the day before re-entry the pain became so severe that three injections of morphine were required for relief. The pain during this attack radiated into the groins.

The temperature was 100.2°F, the pulse 115, and the respirations 20.

There was slight tenderness over McBurney's point, without spasm. No masses were palpable, and rectal examination was negative. The palpable remnant of the prostate was small and symmetrical, without nodules or tenderness. There was no costovertebral-angle tenderness.

Examination of the blood disclosed a hemoglobin of 12.6 gm. and a white-cell count of 18,100. Urinalysis showed a specific gravity of 1.028, a ++ test for albumin and a yellow-brown test for sugar. Ureteral catheter specimens showed 45 to 75 red cells and 1 white cell per high-power field. The non-

protein nitrogen was 29 mg, and the fasting blood sugar 380 mg per 100 cc

Retrograde pyelograms showed normal kidney shadows, and the pelves, calyces and ureters were not abnormal so far as visualized. X-ray films of the chest disclosed a few linear streaks on the lower right and middle portions of the chest. A barium enema revealed numerous diverticula in the sigmoid colon. The appendix did not fill, but on the following day a linear streak of barium consistent with the appendix was seen in the right lower quadrant. A cystogram showed several diverticula of the bladder.

The patient's condition during the first week in the hospital remained unchanged. The diabetes was brought under satisfactory control with insulin. The tenderness in the right lower quadrant persisted, and there was a daily rise in temperature to 101 and 102°F. The tenderness was sometimes prominent along the brim of the pelvis and above the pubis, as well as in the right lower quadrant just medial to and below the anterior superior spine of the ilium. No tenderness or masses were found on further rectal examination. On the eleventh hospital day one observer felt a tender mass in the right lower quadrant, with pain radiating to the scrotum on pressure.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR F A SIMEONE This sixty-nine-year-old man, who had an operation for what was presumably an inflammatory mass, because the mass was tender, had fever, leukocytosis and an increase in the pulse rate. I believe that the problem is to decide the nature of this inflammatory mass.

In reviewing the history of the previous admission we come to the conclusion that this was an ordinary case of benign hypertrophy of the prostate gland and that the perineal prostatectomy had been satisfactory. The patient was relieved and went home after nineteen days. The only unusual point is that he had a nonprotein nitrogen of 122 mg on that admission. The urine was infected, as manifested by the 150 white cells per high-power field. This, together with back pressure, must have led to a certain degree of renal insufficiency. The infection subsided quickly, for the surgeon considered the patient ready for operation on the fourth day of hospitalization. There were no complications after operation and no evidence that a malignant tumor in the gland was missed. He was relieved after this operation for a period of three months, during the second three-month period, however, he began to get into some kind of trouble that was unrelenting and progressive to a point where operation became necessary. He first noted indefinite suprapubic discomfort and pain, — rather nondescript symptoms, which could be accounted for by a number of different conditions, — but the pain gradually became

progressively severer and began to be localized in the right lower quadrant. In addition, he had fever, suggesting that this was probably an inflammatory process. One immediately thinks of appendicitis, — pain in the right lower quadrant is acute appendicitis until proved otherwise, — but this was certainly a strange course for appendicitis to follow. The patient had symptoms for three months. The pain radiated into the right groin. One wonders about the explanation for that. Could this pain in the right lower quadrant have been the pain of, let us say, acute inflammation of the seminal vesicles? Sometimes that pain does radiate into the right lower quadrant and into the groin, but the rectal examination was described as negative. The tenderness in McBurney's point was localized, but without spasm, and no masses were felt over a period of three months. Acute appendicitis of that duration is extremely unlikely. We have the help of the definite statement that the remnant of the prostate was certainly not at fault at that time. There was no costovertebral-angle tenderness to suggest that this was a referred pain from the kidney and upper ureter. The urinalysis was abnormal, of course, in that it showed glycosuria and a ++ test for albumin. We know that the patient had diabetes. Perhaps, with this added infection, the diabetes had got somewhat out of control.

It would be interesting to know for the differential diagnosis what the cellular content of the urine was. We know that the urine from the kidneys was normal. One might expect 45 to 75 red cells per high-power field from catheterization of the ureters and kidneys, but it would be interesting to know how many white cells there were in the bladder urine.

DR GEORGE G SMITH I am sure that there were a good many white cells. There was about 20 ounces of residual urine.

DR SIMEONE It was grossly infected urine?

DR SMITH Yes, slightly cloudy.

DR SIMEONE We have further evidence from the x-ray studies, and I shall ask Dr Wyman to present the films.

DR STANLEY M WYMAN At the time of the first admission the intravenous pyelogram showed a rather diminished function of the kidneys. The left kidney can be outlined lying somewhat low with normal contour. The right kidney is poorly seen but not remarkable. The dye filling is inadequate in both kidneys. There is trabeculation of the bladder and a diverticulum on the left, and a larger, broader diverticulum on the right. There are some changes in the bone structure of the pelvis consistent with Paget's disease. There is calcification in the region of the prostate, which appears to be large. The second film is that of a retrograde pyelogram and shows good filling of the right kidney, with rather faint filling of the left. No abnormality is demonstrated in either kidney. The ureters appear normal.

Dr. SIMEONE Is the irregularity at this point explained on the basis of trabeculation, or can it be a different kind of filling defect?

Dr. WYMAN I think that the irregularity on the right border is probably a diverticulum. I cannot demonstrate it well in these films. We have later films of the bladder that show a definite diverticulum on the left and probably one on the right. At least one lies more on the superior border. This is the shadow of the appendix. The barium enema showed diverticula throughout the sigmoid but no other gross lesion.

Dr. SIMEONE Are these shadows all in the appendix? Does it curve all the way around, or is this shadow in tissue other than the appendix?

Dr. WYMAN I believe that it curls as you suggest. I cannot be sure, however. I think that the appendix lies over the sacroiliac joint.

Dr. SIMEONE It is mentioned in the history that there were shadows in the lung field. I assumed that these were consistent with old atelectasis instead of malignant lesions.

Dr. WYMAN The lung fields show about three linear shadows, which can be focal atelectasis or possibly old infarcts. There is some prominence of the left cardiac border in the region where the pulmonary artery is expected to lie, which probably represents prominence of that artery. I see no evidence of destruction of the ribs or metastatic nodules in the chest.

Dr. SIMEONE The patient's condition changed while he was on the ward, and a palpable mass in the right lower quadrant was felt by at least one observer. It would be interesting to know whether this mass was felt to extend into the pelvis or whether the outlines could be clearly defined and localized in the right lower quadrant. There is probably no mention of that in the record. This mass was not felt by rectal examination, suggesting that it was probably out of the true pelvis.

I believe that with this information we might embark on a differential diagnosis of this inflammatory mass. First of all, could this mass have been entirely independent of the genitourinary tract? We have the information that the patient had diverticula in the sigmoid, but there was no evidence of diverticulitis. Demonstrable diverticula, of course, are fairly common in the general population, but they seldom produce trouble. Perhaps 1 out of 10 cases may develop diverticulitis and cause trouble for the patient. An inflammatory mass may result from diverticulitis, but one would expect it to be on the left side and not on the right, although if the sigmoid was very mobile it might appear on the right side. There is no evidence of such a position of the sigmoid in the examination by barium enema.

Could this have been a late result of acute appendicitis? This was certainly not the usual case of acute appendicitis. However, an acute inflammatory lesion in the appendix may be dependent on

some other more chronic lesion in it. For example, the patient could have had a carcinoma in the appendix, with inflammatory changes about it, increasing in degree until a palpable mass was felt, or he may have had a carcinoid of the appendix. Both these lesions, particularly the former, are extremely rare but might explain this case. The radiation of pain was a little unusual unless we assume that the appendix was lying in the pelvis. The filling of the appendix by means of barium. I consider evidence against its involvement in this process, although filling of the appendix has been observed in acute appendicitis.

Could the patient have had a diverticulum of the cecum? I think that the chances for that are remote, and I shall dismiss it for lack of x-ray evidence. There is no apparent intrinsic lesion of the cecum that might give rise to this inflammatory mass in the right lower quadrant.

Can we relate this mass to the disease of the genitourinary tract? In favor of that supposition is the fact that the patient had trouble with the genitourinary tract, and it would be satisfying to explain this lesion on the same basis. In favor, also, of connecting this disease with the genitourinary tract is the fact that diverticula were demonstrated in the bladder by x-ray study. Were they seen by cystoscopy?

Dr. SMITH Yes, they were.

Dr. SIMEONE It is possible that one of the complications of diverticula of the bladder developed, particularly if there was evidence of persistent infection in the bladder urine. The complications of diverticula are well known. Frequently, stones develop in bladder diverticula. Less commonly, tumors develop in bladder diverticula. Finally, such diverticula may develop peridiverticulitis, with extension into the extraperitoneal pelvic tissues and sometimes actual rupture into the peritoneal cavity, leading to general peritonitis. Against the supposition that this lesion was connected with the disease of the bladder is the fact that no tenderness was elicited by rectum. If this had been an extension of inflammation from the bladder diverticulitis one would expect to feel some tenderness in the right side on the pelvic floor. Taking these possibilities together, the evidence is a little in favor of linking the present lesion with the genitourinary tract. The evidence is against the possibility of a disease referable to the gastrointestinal tract, and it is entirely possible that the patient developed a peridiverticulitis about this one diverticulum, with extension into the right lower quadrant leading to the mass that was palpated by the observer.

The next question that one might consider is whether this was an otherwise uncomplicated form of bladder diverticulitis or a tumor within the diverticulum that had grown and penetrated its walls. That is certainly a possibility, although we have no evidence for it except as a good guess. 1

shall therefore make a preoperative diagnosis of right-lower-quadrant abscess due to extension of a peridiverticulitis of the bladder with a question of tumor within it

DR BRIANT L DECKER I saw this man several times. As I remember the history I thought that it was of shorter duration. He had severe pain associated with nausea of about five weeks' duration, although it is perfectly true that he may have had some discomfort before that. I thought that he had an appendiceal abscess. Just before he came to the hospital he was x-rayed outside, and the appendix was visualized. The note was made that the tip of the appendix was fixed and tender. I also thought that he was given streptomycin while he was in the hospital, and I think that the temperature came down to normal while he was on the streptomycin.

DR SMITH The first mention of the suprapubic discomfort was about three months before the patient died. I had seen him, and when I came back five weeks later the tenderness had increased. I was extremely puzzled why he had this fever and tenderness. I was the one who felt the mass, and I would say that it was small, about 2 or 3 cm in diameter, just to the medial side of McBurney's point. There was nothing felt in the pelvis by bimanual examination. My next guess was that he had an infection of the iliac and aortic lymph nodes that was forming an abscess. He was seen by a surgical consultant, who first did not think that there was any indication for exploration but later did explore him. I think that if Ellery Queen were here he would get a lead from those x-ray films.

DR TRACY B MALLORY Have you anything further to say, Dr Wyman?

DR WYMAN I remember the answer and therefore cannot say anything.

CLINICAL DIAGNOSIS

Ruptured aortic aneurysm

DR SIMEONE'S DIAGNOSIS

Abscess of right lower quadrant from extension of peridiverticulitis of bladder

ANATOMICAL DIAGNOSES

Ruptured arteriosclerotic aneurysm of right iliac artery, with retroperitoneal hematoma

Arteriosclerosis, generalized

Diverticulum of bladder

Diverticulosis of sigmoid

PATHOLOGICAL DISCUSSION

DR MALLORY This man was explored by Dr Sweet, who found an aneurysm at the junction of the iliac artery and the aorta. Two days later the aneurysm suddenly burst, and the patient went into profound shock and died within a few hours of the episode.

At autopsy we found a massive retroperitoneal hematoma, which had dissected into the mesentery of the cecum and ascending colon and also had dissected beneath the parietal peritoneum around the lateral wall of the abdomen. The total hematoma was estimated to contain something in excess of 2 liters of blood. It seems probable that there had been minor leakage before the terminal episode to account for the attacks of acute pain.

The other findings were all historic landmarks and had nothing to do with the symptomatology. There was a slightly hypertrophied heart to go with the mild hypertension. There was a rather severe generalized arteriosclerosis but no dilatation of the aorta itself. The aneurysm was sharply limited to the right iliac artery. The sigmoid was full of diverticula, none of which appeared inflamed. The bladder also contained numerous diverticula that were not inflamed. There was a remnant of prostatic tissue left from the perineal prostatectomy. Have you anything further to add, Dr Smith?

DR SMITH In the x-ray film the right ureter takes a peculiar course as it comes down over the brim of the pelvis. Knowing the answer it is easy enough to put two and two together. It is a slight departure from the normal.

DR WYMAN But it could be caused by a mass other than aneurysm?

DR SIMEONE A retroperitoneal abscess might do it as well as any other tumor.

NEW DIRECTOR OF CHILDREN'S HOSPITAL

Dr. GUY W. BRUGLER, of Cleveland Heights, Ohio, has been named director of the Children's Hospital of Boston, succeeding Dr. Stanton Garfield, who has been acting director of the institution for the past few months.

Dr. Brugler has been assistant director of University Hospitals in Cleveland since 1939. He was on leave of absence during World War II for two years and was with the United States Army Fourth General Hospital in Australia and New Guinea, with the rank of lieutenant colonel. Subsequently, he was executive officer at the United States Army Woodrow Wilson General Hospital in Staunton, Virginia. His executive and administrative experience will be

invaluable in carrying to completion the plans now underway at the Children's Hospital.

At the large teaching institutions it has long been evident that a mere knowledge of medicine is not enough for the head of what is actually a large corporation, nor is executive ability sufficient. Ideally, there should be a man who not only has a knowledge of medicine and is sympathetic with the needs of the professional staff but also has a sound business sense and administrative experience.

The plans of the trustees of the Children's Hospital are national in scope, and their fulfillment will do much to further the art and science of the medical care of this age group. The harmonious liaison between the professional and the executive sides is of the greatest importance, and it is believed that the trustees of the Children's Hospital, by wisely considering this fact, have made a good choice. We wish them all success and believe that in the appointment of their new director they have taken an important step in furthering their plans and ideals. The successful fruition of their project will result in great benefit, not only to greater Boston and New England but also to the country.

CHEMOTHERAPY OF TUBERCULOSIS

THE successful use of sulfanilamide and its derivatives and the demonstration of the curative effect of penicillin for many types of infections have led, quite naturally, to renewed efforts to discover a true cure for tuberculosis. Sulfanilamide and those of its derivatives that have proved most successful against the common coccil and bacillary infections have been shown to be bacteriostatic in vitro but have not given encouraging results in the treatment of tuberculous infections. The studies of Rich and Follis on the effects of sulfanilamide in experimental tuberculosis in guinea pigs, although they showed only minimal effects from this agent, have nevertheless laid the groundwork for the testing and screening of various agents for their therapeutic effects in this disease. Modification and standardization of the method by Feldman and his associates have brought out the effectiveness of a succession of chemicals of the sulfone group, including Promin, Diazone and Promizole, each of which gave promise

of only limited usefulness owing to the toxic effects of prolonged treatment with the large doses that are required for any therapeutic benefit²⁻⁵. The same methods and others involving infections in mice and even in chick embryos have since been used to establish the effectiveness of streptomycin in tuberculosis.

This is not the first or only period, however, when chemotherapeutic success, apparent or real, in the treatment of one type of infection or another has been accompanied by clinical trials and enthusiasm for the same or related agents in tuberculosis. A timely comprehensive and critical review of these and other aspects of the chemotherapy of tuberculosis was ably presented by Hart⁶ in his Mitchell Lecture delivered last summer before the Royal College of Physicians in London. This lecture gives a chronologic account of the various agents and classes of agents that have been used during the past century. Although the lecturer's summaries and comments on some of the older types of therapy are of interest from the point of view of historical perspective, his analysis of the present status of the sulfones and of streptomycin and his outlook for the future are particularly significant and worthy of comment.

The experiences to date with the sulfonamides and related compounds are summarized somewhat as follows. They have a more deterrent effect on experimental tuberculosis in some species than any drugs previously tried. Although early established lesions may regress and even be resolved, the eradication of virulent infection, a necessary criterion in the acute or subacute disease of the hypersensitive guinea pig, has not been attained. In man the small number of cases treated, in the absence of simultaneous matched controls in most trials hitherto reported, has made the assessment of these drugs difficult, but the results do not appear so favorable as those in the guinea pig. This is explained either by a lower tolerance, with the result that adequate dosage is difficult to achieve because of the risk of objectionable symptoms or by the possibility that the type of disease is different or that the drug is altered in the body and thus inactivated. At best, some benefit in recent exudative lesions is attributable to these

drugs, but no regression of the disease to quiescence or cure has been demonstrated. The clinical use of these chemotherapeutic agents is likely to be limited to local use or to their employment in combination with other substances, such as streptomycin.

A few years ago, interest in the chemical analysis of the mycobacteria had focused on their fatty structure. Because of this, emphasis was placed on a "lipophilic" approach to the chemotherapy of tuberculosis and search among antiseptics was centered on fat-soluble compounds. Hart properly points out that the results with water-soluble sulfones and with streptomycin emphasize the fact that the mycobacteria, despite their fatty structure, are apparently more susceptible to water-soluble antiseptics than to fat-soluble compounds, thus, the lipophilic approach to chemotherapy does not appear to be the only one, nor may it be the most fruitful.

There are many reasons for investigating the aromatic group of organic compounds for their possible use against tuberculosis. Some have been tested because of their relation to the sulfones, whereas others, such as the naphthaquinone derivatives, represent an attempt to interfere with bacterial metabolism through a structural similarity to hypothetical growth factors or growth stimulants of the vitamin K type. Others were studied in a search for growth inhibitors based on the increase in oxygen uptake by washed suspensions of tubercle bacilli produced by benzoic and salicylic acids and certain other aromatic compounds. Such investigations suggested that these or chemically similar substances may play a part in the normal oxidation of bacilli and that substituted benzoates and salicylates may interfere with the oxidation and so inhibit growth*. Certain dyes have also been used because of promising earlier results, and some of the acridine compounds have been tested because of their clinical value in protozoal and bacterial infections, whereas others were employed because they were wax-soluble.

None of these substances, however, have as yet given any evidence of efficacy, combined with safety, in human tuberculosis, although some of the clinical

*Several papers reporting encouraging results from the use of para-aminosalicylic acid both in experimental infections and in clinical tuberculosis have appeared recently in the Swedish literature. Studies of this compound are now also under way in some laboratories and clinics in this country.

inals are not yet complete. One compound, Calciferol, deserves particular mention, however, several French and British workers are noted as having observed good results in lupus vulgaris with this substance used in high dosage. Its exact mechanism of action has not been clarified, and these clinical results require confirmation. Although serious toxic effects have thus far not been reported, the possibility of calcific deposits in tissues must be watched. A long list of antibiotics from natural sources, all of which have antibacterial action against the mycobacteria, is given. The sources of most of these antibiotics are species of *Aspergillus* and *Streptomyces* and organisms related to *Bacillus subtilis*. Among these agents, however, only streptomycin is obtaining a full therapeutic trial. Hart's evaluation of streptomycin is based on the early results. Experimentally, these seem to be much more favorable in guinea pigs than in mice. He believes that the effects in human beings justify cautious enthusiasm. The disadvantages are recognized, particularly the development of resistant strains during treatment, the necessity for prolonged therapy with large doses and the deleterious effect of an acid medium. For these reasons it is thought that other chemotherapeutic agents may prove to be more desirable for use in tuberculosis even should streptomycin justify its present hopes.

The chemical and antibiotic problems involved in the discovery of an effective chemotherapeutic agent, especially in tuberculosis, are ably discussed. Hart states that these two paths should ultimately converge—"for knowledge of the chemical structure of antibiotic substances may promote laboratory synthesis of active related compounds, while knowledge of the point of interference of such substances may give new information on the essential metabolism of the tubercle bacillus and lead to the purposeful creation of simpler synthetic antimetabolites." It is improbable, however, that success in chemotherapy will supersede all the tried and tested methods of control, acquired through the years, that are applied to the patient, to his family and to the community. Rest can be expected to remain the foundation of treatment, surgical methods will be needed in certain types of cases, and the state of housing and of nutrition may be expected to

continue to influence the trend of tuberculosis incidence and mortality. Hart concludes "There are in the world perhaps between ten and twenty million sufferers from active tuberculosis. In order to reduce this inroad on world health we shall probably need most of the reasonable measures—social and economic, preventive and therapeutic—that we possess now or that we can acquire in the future. The attack will remain multiple, the tactics will change."

A HUNDRED YEARS AGO

A revolution is very much needed in the manufacture of boots, the modern fashion of high heels being positively injurious to the frame work of the feet. If the foot is tilted from the top of a high-heeled boot, the toes are pressed forward, down an inclined plane, which distorts them, and leads to the formation of corns. In multitudes of young men, the pressure is so great forward, that the large toe joint and the little toe metatarsal articulations are affected with bunions, swell, and sometimes remain permanently enlarged and sensitive. All beauty and symmetry are forever lost, and to the last days of an extreme old age, a foot thus tortured into a state of disease will be both sore and distorted. Something might also be said of ladies' shoes, with high heels, but as they are victims to other and even worse effects on the chest from a determination to improve upon nature, their case is deferred for another occasion.—The introduction of a foreign body into the larynx, or trachea, is an accident generally attended with much terror and distress at the time, and often followed by symptoms of an alarming, and sometimes of a fatal, character. The occurrence of this accident is rendered more frequent, both by the heedlessness of children, and the foolish habit indulged in by many grown persons, of keeping pins, nails, and other like bodies, in the mouth. Dr. J. Mason Warren reports three interesting cases the first was a child, who while in the act of laughing, drew a common garden bean, which she had in her mouth, into the

trachea, the second, a little boy, was suddenly seized with a choking and violent cough which he said was caused by a blacksmith's nail in his mouth, the third was a young woman who had been so unfortunate as to get a pin in her larynx, after undressing a child and incautiously putting the pins in her mouth as they were removed from its dress. As Dr. Warren says, a question always arises in the mind of the surgeon called to an instance of this kind as to the propriety of opening the windpipe and attempting the extraction of the foreign body without delay. If the nature of the symptoms be urgent, and immediate suffocation is threatened, there is no alternative but to proceed at once with operation. But if the violent paroxysm, which at first threatened life has subsided, and the substance has settled into one of the bronchial tubes, causing only occasional disturbance, the question becomes one of more difficult solution. Dr. W. avers, should another case of this kind occur to him, he should at once perform the operation of tracheotomy, and by a free use of ether, attempt to allay the irritability of the air passages, so as to allow a more easy exploration by instruments, than is generally afforded in the natural state. — At the annual meeting of the Boylston Medical Society, November 22d, 1847, the following gentlemen were elected officers for the ensuing year: Luther Parker, Jr., M.D., *President*, James W. Stone, M.D., 1st *Vice-President*, Daniel D. Slade, M.D., 2d *Vice-President*, Z. B. Adams, M.D., *Treasurer*, James C. Neilson, *Secretary*, and Edwin Leigh, *Librarian*. Drs. John Ware, Geo. Hayward, Enoch Hale, Z. B. Adams, G. C. Shattuck, Jr., John Homans, Jacob Bigelow, *Trustees*. — A law is needed in Massachusetts requiring every druggist, apothecary and wholesale dealer who desires to keep on hand drugs which may be deadly poisons, to procure a license to do so from the municipal authorities. Perhaps we may be censured for being over careful, and even whimsical in the scheme here proposed for protecting the people, but if so, we have a valid apology. Life is too precious to be subjected to the contingency of death when all danger might be avoided by a simple process. — Dr. C. A. Harris of Baltimore and Drs. Buckminster Brown, and W. T. G. Morton of Boston give us intelligence from Edinburgh of Prof. Simpson's discovery of chloroform as a substitute for ether in preventing the pain of surgical operations. In preparing and administering the substance to a patient, Dr. Morton obtained the polite assistance of Dr. E. R. Smilie, a person of some reputation in chemical science. A lady opportunely arrived at Dr. M.'s office for the purpose of inhaling ether, and having three teeth extracted under its operation. After inhaling ether and allowing its effect to pass away, about one ounce of freshly made chloroform was put upon the sponge previously freed from the effect of the ether, and administered by the usual method. The teeth were

extracted without the knowledge of the patient, Dr. M. says the effects were similar to those produced by ether. The perfume of the new vapor is said to be not unpleasant, but the reversal, and the odor of it does not remain for any length of time obstinately attached to the clothes of the attendant, or exhaling in a disagreeable form from the lungs of the patient. Its exhibition is said to be accompanied by no sickness, vomiting, headache, salivation, or uneasiness of chest. — Extracted from the *Boston Medical and Surgical Journal*, December 1847.

R F

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CANCER AND OTHER CHRONIC DISEASES

In the annual report of the Division of Cancer and Other Chronic Diseases certain figures pertaining to the cancer clinics are interesting. The attendance increased from 1927, the first year of the clinics, until 1940, when it reached a maximum of 5490 new patients, 32 per cent of whom had cancer. During the war years there was a decided drop in attendance, 1943 being the year having the smallest number. The trend has again been reversed, although in 1946 the total attendance of 4026 patients, with 35.4 per cent having cancer, is considerably less than that in 1940.

There has been an increase in the percentage of persons who delayed less than a month between the first appearance of symptoms and first consultation with a physician. In the period 1930-1935, 14 per cent delayed less than one month, and in 1946, 23 per cent. There was considerable difference in the delay depending on the location of the cancer.

In 1946 more patients came to the cancer clinics upon recommendation of physicians than in any previous year, the percentage being 88.8. Of the recommendations made at the clinics 88.5 per cent were carried out within a month.

There has been a great increase in the use of the Tumor Diagnosis Service. In 1926 a total of 2484 specimens were examined, and in 1946, 5264 specimens. In 1926, 371 physicians and 52 hospitals and in 1946, 809 physicians and 108 hospitals made use of this service.

During the war, teaching clinics decreased both in number and in attendance. Although they have not returned to their original extent, 20 clinics, with a total attendance of 781 physicians, were held in 1946.

Several of the tables from the annual report have been multigraphed and are available to the physicians of Massachusetts upon request to the Division of Cancer and Other Chronic Diseases, Massachusetts Department of Public Health, 100 Nashua Street, Boston 14.

THE CYTOLOGY TEST FOR CANCER

The Massachusetts Department of Public Health, in co-operation with the cancer clinics, has been carrying on an investigation of the cytology test for cancer of the uterus. This study, financed in part by the Commonwealth Fund, was inaugurated to determine the incidence of cancer of the uterus in women without gynecologic symptoms, whether this test is of sufficient value to warrant its continued use in the cancer clinics and whether it should be offered to all physicians in Massachusetts as another diagnostic service. An advisory committee for this study was appointed, consisting of Drs. Thomas Almy, John Fallon, Reginald Fitz, Maurice J. Remont-Smith, Edward G. Huber, Joe V. Meigs and Shields Warren. Since the formation of this committee Dr. Almy and Dr. Huber have died.

The committee recommended collecting vaginal smears from women attending the cancer clinics, from both those with and those without gynecologic symptoms. Biopsies were obtained from as many patients with positive smears as possible. In some cases the smear diagnosis was confirmed, in others, it was not. It is desired that three years after the original smear these women have a repeat smear as well as a pelvic examination, to determine whether or not cancer is present. The follow-up smear should disclose whether the unconfirmed positive smears were falsely positive, as well as whether the negative smears were falsely negative.

The first half of the study has been completed, and preliminary indications are that the true rate of uterine cancer among symptom-free women lies between 2 and 4 per 1000, whereas that among women with gynecologic symptoms may lie between 75 and 100 per 1000.

Until the study is completed this diagnostic procedure will not be offered to physicians in the State, but so far as facilities permit, the examination of smears collected at the clinics will continue.

MISCELLANY

NOTES

Dr. Walter S. Burrage of Boston, has been elected to the board of trustees of the American Allergy Fund, a national foundation for the support of scientific research and public education in the field of allergy. Dr. Burrage is assistant professor of medicine at Harvard Medical School and chief of allergy for the Veterans Administration, Branch No. 1. He is consultant at the United States Naval Hospital in Chelsea, physician at New England Deaconess Hospital and consultant at Massachusetts Eye and Ear Infirmary in Boston.

The American Allergy Fund has its headquarters in Cleveland, Ohio, and its president is Dr. Jonathan Forman, editor of the *Ohio State Medical Journal*. Dr. Sanford B. Hooker of Boston University School of Medicine, is an associate of the fund and a member of its scientific advisory council, which is headed by Dr. A. J. Carlson of the University of Chicago.

Dr. Samuel C. Harvey, formerly William H. Carmalt, Professor of Surgery and chairman of the Department of Surgery, Yale University School of Medicine, was recently appointed professor of surgery with special reference to oncology (the study of tumors) at the School of Medicine. The new professorship is supported by grants from the National Cancer Institute of the United States Public Health Service and Mr. Robert E. Hunter of Pasadena, California. Dr. Harvey will assume responsibility for stimulating investigation of the problem of cancer and for training medical students and physicians in the special problems involved in the diagnosis, treatment and care of patients with this disease. His successor in the Department of Surgery is Dr. Gustaf F. Lindskog, formerly associate professor of surgery.

NORWOOD HOSPITAL

At a meeting of the senior staff of the Norwood Hospital on November 7, the following resolution was passed:

The Norwood Hospital Staff notes with regret the death of our late colleague Dr. Louis Arkin.

Dr. Arkin was a member of the Associate Staff of the Norwood Hospital from March 1945, to his death on October 1, 1947. In that time, he gained the respect and affection of the members by his ethical conduct and good fellowship. The Norwood Hospital Staff expresses deep regret at his passing and extends sincere sympathy to his bereaved relatives.

It is hereby resolved that a copy of this action be included in the records of the Norwood Hospital Staff and similar copies be sent to his nearest relative and published in the *New England Journal of Medicine*.

CORRESPONDENCE

RESTORATION OF LICENSE

To the Editor: At a meeting of the Board of Registration in Medicine held October 17, it was voted to restore the registration to practice medicine in this Commonwealth to Dr. Morris J. Kupper, 961 Blue Hill Avenue, Roxbury, whose registration was revoked October 18, 1944.

State House
Boston

LEAD PAINT STILL A HAZARD

To the Editor: In the November 6 issue of the *Journal* there appears an editorial entitled "Epidemic Lead Poisoning." This title is supported by the facts presented and unquestionably explains how large numbers of infants and children may become victims of this disturbance at any one time, or as one might say, at any one exposure. The main point of the editorial is well taken and most assuredly merits the attention of the medical profession. However, it is unfortunate that the editorial places lead poisoning resulting from the ingestion of lead paint obtained from toys, cribs and so forth, and chewed by infants and young children in the background. Actually, this source of lead poisoning continues to be a real and not a mythical danger. A review of the cases of acute or chronic plumbism occurring among this age group will verify this statement. The manufacturers may not employ lead paint to painting their wares, but what type of paint does the average adult select in repainting cribs, toys and interior woodwork? There is adequate clinical evidence that he employs lead paint, and thus the young patients suffering from plumbism continue to present themselves at hospitals. They do not appear in epidemic proportions, but the total number over a given period proves startlingly high.

It therefore does not appear, as suggested in the editorial that emphasis has sometimes been mistakenly placed by the medical profession on the source of lead in lead poisoning occurring among infants and children. One case of acute polymyositis does not make an epidemic, but its occurrence is disturbing to the parents and, as with lead poisoning, may prove disastrous if not fatal to the victim. It is the little things that count—even if it is only an old toy repainted with lead paint by a devoted parent.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Arthritis and Related Conditions Edited by Theodore F. Bach, M.D., associate in medicine, Graduate School of Medicine, University of Pennsylvania, and chief, Arthritic Clinic, Abington Memorial Hospital, Abington, Pennsylvania. 8°, cloth, 472 pp., with 139 illustrations. Philadelphia: F. A. Davis Company, 1947. \$6.50

Deep Analysis: The clinical study of an individual case By Charles Berg, M.D. (Lond.), D.P.M., fellow of the British Psychological Association, physician, British Hospital for Functional Mental and Nervous Disorders, and physician, Institute for Scientific Treatment of Delinquency. 8°, cloth, 254 pp. New York: W. W. Norton and Company, Incorporated, 1947. \$3.50

Osteotomy of the Long Bones By Henry Milch, M.D., consulting orthopedist, Maimonides Hospital, and attending orthopedic surgeon, Hospital for Joint Diseases and Riverside Hospital, New York City. 8°, cloth, 294 pp., with 181 illustrations. Springfield, Illinois: Charles C. Thomas, 1947. \$6.75

Textbook of the Nervous System: A foundation for clinical neurology By H. Chandler Elliott, M.A., Ph.D., assistant professor of anatomy, Medical College of the State of South Carolina. With an introduction by Wilder Penfield, M.D. 4°, cloth, 384 pp., with 158 illustrations. Philadelphia: J. B. Lippincott Company, 1947. \$8.00

Cineplasty By Henry H. Kessler, M.D., Ph.D., orthopedic and amputation consultant, Office of Vocational Rehabilitation, and member of New Jersey Rehabilitation Commission. With a foreword by Ross T. McIntire, Vice-Admiral (MC), U.S.N., the Surgeon General, United States Navy. 8°, cloth, 201 pp., with 199 illustrations. Springfield, Illinois: Charles C. Thomas, 1947. \$6.75

NOTICES

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

A meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore, Boston, on Wednesday, December 17, at 8 p.m. Dr. Sidney Licht, editor of *Occupational Therapy and Rehabilitation*, will speak on the subject "Clinical Diagnostic Measures in Physical Medicine."

Physicians, physical therapists and nurses are invited to attend.

AMERICAN COLLEGE OF SURGEONS

Six sectional meetings of the American College of Surgeons will be held in 1948. The date and location of each meeting is as follows: January 20 and 21, Commodore Perry Hotel, Toledo, Ohio; January 26 and 27, Ansley Hotel, Atlanta, Georgia; January 30 and 31, Oklahoma Biltmore Hotel, Oklahoma City; March 1 and 2, Cosmopolitan Hotel, Denver, Colorado; March 15 and 16, Hotel Nicolle, Minneapolis, Minnesota; May 17 and 18, The Nova Scotian, Halifax, Nova Scotia. Fellows of the College, the medical profession at large and hospital personnel are invited. Each meeting will be two days in length and will include conferences for hospital personnel and sessions for the medical profession. The showing of medical motion picture films will begin each day's program at 8:30 a.m. There will be luncheon meetings each day and a dinner meeting on the first evening followed by a symposium on cancer. Panel discussions on scientific subjects, led by internationally known authorities in each field of surgery, will be held each morning and afternoon.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, DECEMBER 18

FRIDAY, DECEMBER 19

*9-10-10:00 a.m. Gastritis. Dr. Seymour Gray. Joseph H. Pratt Diagnostic Hospital.

*10:00 a.m.-12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital.

MONDAY, DECEMBER 22

12:00 p.m. Clinicopathological Conference. Margaret Jewett Hall, Mount Auburn Hospital, Cambridge.

*12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

TUESDAY, DECEMBER 23

*12:15-1:15 p.m. Clinicoradiological Conference. Peter Bent Brigham Hospital.

WEDNESDAY, DECEMBER 24

*12:00 p.m. Grand Rounds and Clinicopathological Conference (Children's Hospital). Amphitheater, Peter Bent Brigham Hospital.

*2:00-3:00 p.m. Combined Clinic by the Medical, Surgical and Orthopedic Services. Amphitheater, Children's Hospital.

*Open to the medical profession.

ANESTHESIA WITH INTRAVENOUS PENTOTHAL SODIUM AND LOCAL NERVE BLOCK IN GYNECOLOGIC SURGERY*

JAMES C. McCANN, M.D.†

WORCESTER, MASSACHUSETTS

THE use of Pentothal Sodium as an intravenous anesthetic agent has found wide acceptance in the field of gynecologic surgery. This is probably related to the following basic considerations: the high incidence of satisfactory muscular relaxation in this field of surgery as a consequence of antecedent pregnancy, and the minimal intensity of reflex stimulation of respiration from surgical trauma in the areas of lumbar and sacral autonomic nerve supply during pelvic surgery. Quantitative and pneumographic observations made during the past three years in pursuance of a routine surgical practice in which intravenous Pentothal Sodium combined with local nerve block has provided the anesthetic of choice in 60 to 70 per cent of 2000 cases of general surgical procedures have elucidated the variations in reflex stimulation of respiration not only in the peripheral area of distribution of the nerves from the lumbar and sacral segments of the cord but also in the areas of distribution of the peripheral nerves derived from the other neurologic segments.

A sufficient volume of gynecologic surgery is included in this over-all experience to warrant a detailed evaluation of this combined method of anesthesia. In the total of 2000 general surgical cases operations were performed under Pentothal Sodium in 450 cases that were in the field of gynecologic surgery. Of this selected group, there were 236 intra-abdominal major gynecologic procedures, 40 major vaginal procedures (vaginal hysterectomy, Fothergill operation and interposition) and 170 minor vaginal procedures. Any analysis of such an experience should be made in the light of the major physiologic facts revealed in this study as they relate to the neurospecific segmental character of the traumatic reflex stimulation of respiration in the several neurologic segments of the body. Specifically, three neurologic segments are trauma-

tized surgically during surgery in the pelvis. The incision and closure of the abdomen, as well as the retraction of the abdominal viscera upward for exposure of the pelvis, are carried out in the strongly reactive areas of distribution of the thoracic nerves, the removal of the uterus itself is carried out in two different neurologic regions of minimal reactivity—the areas of the lumbar and sacral autonomic nerves.

In general it may be stated with reference to the over-all quantitative requirements of Pentothal Sodium in any particular surgical procedure, that the rate of administration will be related to two determining factors: the need for the drug in any particular case as determined by the rate of metabolic destruction of the drug, and the duration of the operation and its type according to the neurologic segment in the peripheral area of distribution of the nerves of which the operation occurs. Detailed quantitative studies have revealed no other important determinant of the rate of utilization of the drug, such as age, sex or weight. Patients of the same sex, age and weight who undergo identical operative procedures show extreme variations in the quantity of Pentothal required for anesthesia. This can be related only to the varying individual rates of destruction of the drug and to the varying intensities of traumatic reflex stimulation of respiration. The prolonged operations entail progressive severance of pathways of nerve conduction that also progressively reduces the number and intensity of stimulating pain impulses transmitted centrally to the respiratory center. As a corollary, this effect steadily reduces the reflex stimulation of respiration and thus diminishes the quantity of Pentothal required to control respiration. With adequate evaluation of these factors there is no residual concrete evidence to indicate the occurrence of any so-called "cumulative action" of the drug. On the contrary, with reflex factors well controlled by procaine field block, there seems to be ample evidence of fixed, level, basic need for the drug in each patient, even over an extended period.

*Presented at a meeting of the New England Obstetrical and Gynecological Society, Worcester, Massachusetts, May 29, 1946.
†Harbor St. Vincent's Hospital.

All intra-abdominal pelvic operative procedures in this group of gynecologic cases were carried out under anesthesia by combined intravenous drip of Pentothal Sodium in a 1 per cent solution and local nerve block by procaine in a 1 per cent solution. The Pentothal was administered by infusion during the induction period at a rate of 250 drops a minute until the patient lost consciousness and stopped counting. No further administration of the drug was made until the early irregularities of respiration returned to normal. Subsequent induction fractions were given in quantities of 10 cc for patients under fifty years of age, with a minute intervening between fractions, or in quantities of 5 cc in thin, small patients over fifty years of age, with two minutes intervening. These induction fractions were repeated for an average of two to four fractions, or for as many fractions as were needed to reach the point of complete induction of surgical anesthesia. Induction was never carried beyond the point of loss of motor response to a pinch of the inner arm or axilla with an Allis forceps, except as further administration of the drug was balanced against the stimulus of respiration by the surgeon who was making the incision. The final end point of complete induction was taken as that at which, in the unconscious patient, there was neither motor response nor undue reflex stimulation of respiration in response to sectioning the body wall.

Subsequent maintenance fractions of Pentothal are administered during the course of the surgical procedure at the rate of 130 drops a minute, each fraction being given when recurring reflex stimulation of respiration by surgical trauma manifests itself. Care is taken never to permit an anesthetized patient to re-enter a too light plane of anesthesia in which the intensity of the reflex stimulation of respiration, particularly in the thoracic-nerve segment (the base of the neck to the symphysis pubis), would handicap the surgeon by disturbing the quiet of the operative field. These subsequent maintenance fractions are limited to quantities of 5 cc with at least one minute intervening between fractions, if the complete induction dose has been less than 75 cc (0.75 gm). In contrast, when the induction dose is over 75 cc, subsequent maintenance fractions of 10 cc each are administered with at least a minute intervening. These fractions are given only to the point of re-establishing control of the reflexly stimulated respiration, the one exception being that, when a local procaine field block (anterior splanchnic, intercostal or pelvic nerve) supplements the Pentothal anesthesia, it should be determined empirically whether the fractions should again be reduced to 5 cc quantities because of the diminished reflex stimulation of respiration. In the abdominal approach to pelvic surgery there were a handful of operations done in the presence of extreme obesity in which Pentothal had to be dis-

continued and ether substituted because of the overly active stimulation of respiration by upward retraction of the abdominal viscera against the diaphragm. A few cases were rejected for Pentothal anesthesia primarily because of an anticipated unsatisfactory respiratory experience from this compression reflex that is discussed below. In vaginal operative work a method of continuous administration of Pentothal and ether is used in which after the usual induction dose of Pentothal in 1 per cent solution, the drug is administered continuously in a 0.5 per cent solution at the rate of 30 drops a minute. Frequently, a 0.25 per cent solution is used at the rate of 30 drops a minute to avoid respiratory depression. Ether is administered continuously at the rate of approximately 28.3 gm an hour. These minimal quantities of drug in combination provide an extremely quiet, satisfactory anesthesia for vaginal operative work. In combined vaginal and abdominal pelvic surgery after a 2-gm ceiling of Pentothal has been reached, ether alone is used to complete the operation.

Transincisional procaine block of the intercostal nerves to the lower half of the rectus muscles is carried out after complete incision of the skin, subcutaneous tissues and fascial anterior layer of the rectus sheath. Injection of these nerves is made at the outer border of the rectus sheath at points 1.5 cm apart, 2 or 3 cc of procaine solution (1 per cent) being injected at each point. An additional 5 cc is injected deeply into each rectus muscle at the upper angle of the incision aiming at the outer sulcus, where the intercostal nerves enter the sheath. This transincisional procedure requires from 30 to 40 cc of procaine solution, and is easily accomplished in two or three minutes. It provides a flaccid paralysis of the rectus muscles such as obtains in spinal anesthesia or deep third-stage ether anesthesia. Only respiratory inactivation of the other abdominal muscles, which is easily accomplished by Pentothal, and not paralysis is needed to provide a satisfactory operative field. In cases in which a pelvic field block is done, 4 cc of procaine is injected retroperitoneally in the region of the superior hypogastric plexus (lumbar-autonomic) immediately below the promontory of the sacrum. An additional 4 cc is injected deeply in the region of the inferior hypogastric plexus (sacral-autonomic), each round ligament is injected at its outer end with 1 cc of procaine solution, at each side of the cervix 3 cc of procaine is injected into the paracervical and parametrial tissues in which the large ganglions of Frankenhäuser lie. Although it does not greatly reduce the quantity of Pentothal used, such a block assures immobility in the abdominal field by completely eliminating reflex activation of the abdominal muscles during expiration as a part of the traction reflex discussed below.

Relaxation of the rectus muscles is routinely produced by procaine nerve block in this method.

Relaxation is never required of Pentothal alone, since muscular relaxation is frequently not achieved under Pentothal alone at a plane of anesthesia that is quite satisfactory in every other respect, conversely, to require muscular relaxation in such cases sometimes entails precipitating a degree of respiratory depression that is wholly unnecessary from all other aspects of a satisfactory degree of anesthesia. The routine use of rectus sheath block is justified by a study of the incidence of full, flaccid muscular relaxation in a series of 100 consecutive cases that had been carried to a satisfactory plane of surgical anesthesia in all other respects (unconsciousness, and the absence of motor response or of undue reflex stimulation of respiration by surgical trauma). An analysis of these cases shows that a striking relation exists between a satisfactory degree of relaxation of the rectus muscles under Pentothal anesthesia alone and the experience of a previous pregnancy with its associated stretching of the abdominal muscles. Of 36 female patients exhibiting a satisfactory degree of relaxation of the rectus muscle at an otherwise adequate plane of anesthesia, 26, or 72 per cent, had experienced a preceding pregnancy. Of 35 female patients who failed to exhibit a satisfactory degree of relaxation at an otherwise satisfactory plane of anesthesia, there were 25, or 71 per cent, who had not experienced previous pregnancy. In a group of 29 male patients, all spared by nature from this physiologic stretching of the abdominal muscles, there were only 3, or 13 per cent, who exhibited satisfactory muscular relaxation, whereas 26, or 87 per cent, failed to exhibit such relaxation. A second grouping of the figures, which encompassed 41 female patients who were subjected to identical surgical procedures through similar incisions (appendectomy through a low right paramedian incision), all reflex factors involved being thus stabilized, showed that of 13 patients who exhibited satisfactory muscular relaxation at the usual plane of anesthesia, 11 had experienced previous pregnancy, on the other hand, of the 28 patients who failed to exhibit satisfactory muscular relaxation, 23 had not previously been pregnant. Procaine injection of the rectus muscles avoided need of a deep plane of Pentothal anesthesia, with its concomitant depression of respiration, and achieved an eminently safe type of anesthesia.

The more powerful intra-abdominal reflexes that condition muscle tensing can also be controlled by the supplemental use of cyclopropane, ether or curare with Pentothal instead of procaine, as shown by the pneumograph, but not so effectively with nitrous oxide and oxygen. In a group of 450 gynecologic operations carried out under combined Pentothal and local nerve block there were only 2 deaths, both of which occurred during convalescence. One was due to an unannounced massive pulmonary embolus, and the other to fatal uremia secondary to

diabetic acidosis. This gives an over-all mortality of 0.4 of 1 per cent for the entire group and 0.7 of 1 per cent for the major surgical procedures. No pulmonary complications other than infarcts of embolic origin were encountered.

A quantitative study of the effect of procaine field block in pelvic surgery on the rate of utilization of Pentothal was made. This study parallels two previous reports, one in cholecystectomy (anterior splanchnic block) and the other in radical mastectomy (intercostal nerve block). Two series of hysterectomies were investigated for comparison. In the first, 10 hysterectomies were done under Pentothal and rectus sheath block alone without procaine field block of the pelvis, in the second, 10 hysterectomies were done with supplemental procaine field block of the pelvis, as described above. The two series are compared with each other only on the basis of the time consumed and the quantity of Pentothal administered during the performance of the hysterectomy per se. This excludes the time interval and the drug administration pertaining to the opening and closure of the abdomen, and the packing up of the viscera. This restriction is necessary to eliminate the highly reactive and variable stimulation of respiration by trauma in the thoracic zone in which the opening, closure and retraction occur, and to limit the study to the effect of reflex stimulation of respiration from trauma in the lumbosacral autonomic zone, which is the neurologic zone involved in a hysterectomy. In the hysterectomies done under Pentothal anesthesia without field block of the pelvis, the average rate of utilization of Pentothal during the hysterectomy per se was 0.006 gm a minute. In the hysterectomies done under Pentothal anesthesia supplemented by procaine field block of the pelvis the rate of utilization of Pentothal was 0.003 gm a minute. This represents a reduction of 50 per cent in the need for Pentothal as a result of the peripheral blockage of all pain impulses initiated by trauma in the pelvis from impinging on the respiratory center. This result parallels the reported reduction of 50 per cent in the need of Pentothal effected by local procaine field block in cholecystectomy (anterior splanchnic block) and in radical mastectomy (intercostal block). The low rate of utilization in the mildly reactive lumbosacral segment (0.006 gm a minute) for hysterectomy stands in the striking ratio of 1:4 when compared with the calculated rate of utilization (0.024 gm a minute) in the highly reactive field of the thoracic segment for cholecystectomy. The minimal intensity of the stimulating impulses arising in the lumbosacral autonomic area is further emphasized by the fact that only 14 per cent of the total amount of Pentothal sodium administered for the entire surgical episode was given during the period of hysterectomy proper, whereas the remaining 76 per cent was required for induction, opening and closing of the

incision (thoracic segment) These indirect quantitative measurements of the segmental differences of intensity of the stimulating impulses that reflexly activate respiration only serve to verify the appended observations on the intensity of segmental reflexes recorded by the pneumograph

Pneumographic studies carried out in the operating room during the course of these studies have demonstrated the specific character of the respiratory response to pain impulses initiated by trauma in the area of distribution of the nerves from the several neurologic segments of the body (cranial, cervical, thoracic, lumbar and sacral) In the cervical segment there is negligible reflex stimulation

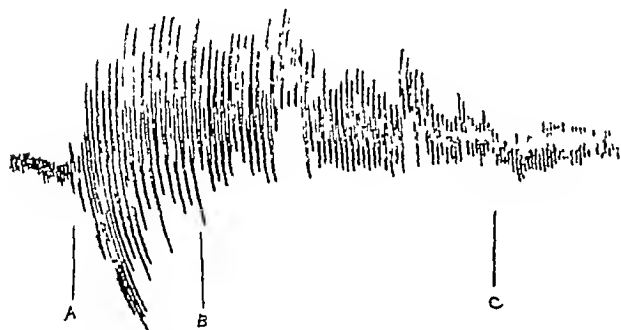

FIGURE 1 Thoracic Somatic Reflex

This graph demonstrates the normal respiratory curve under Pentothal to point A, at which the incision is started. A to B shows the sharp reflex stimulation of respiration with an accentuated and prolonged expiratory phase (upstroke of pen) by pain impulses from incision. The abdominal muscles vigorously contract during expiration, causing muscular rigidity and disturbed abdominal relaxation. Control of reflex stimulation (B to C) with Pentothal is effected by suppressing the expiratory neurons and inactivating (not paralyzing) the abdominal muscles. This restores abdominal relaxation. From C easy, adequate respiration with a quiet abdomen prevails.

of the inspiratory side of respiration in the somatic plane, there is practically no stimulation of respiration in the visceral plane (thyroidectomy). In the thoracic zone (the base of the neck to the symphysis pubis) there is an intense reflex stimulation of the expiratory side of respiration by trauma, both in the somatic and in the visceral plane. This response far exceeds that noted in any other segment of the body. Its importance lies in the fact that stimulated respiration in this segment activates the abdominal muscles in the role of accessory expiratory muscles of respiration, their activity being identical with that which occurs during the forced expiration of heavy exertion or dyspnea. This activity disturbs abdominal relaxation and limits access to the operative fields. In the thoracic visceral zone the reflex muscular response may be of such magnitude in light planes of Pentothal anesthesia as to precipitate an expiratory arrest of respiration during the period of traumatic stimulation, leading to increased production of carbon dioxide from muscular contraction and to deficient oxygen intake, both of

which may contribute to transient cyanosis. Such anoxia is due not to the action of the drug *per se* but to prolonged expiratory muscular response to trauma in a too light plane of Pentothal anesthesia.

A pneumographic recording made while the skin of the lower abdomen (thoracic segment) was being incised showed that, after a period of a quiet, unstimulated run, the trauma of an incision evokes a sharp respiratory response chiefly on the side of expiration (Fig 1). This stimulation of respiration, which activates the abdominal muscles to prolonged and forceful contractile efforts, requires significant amounts of Pentothal to control the stimulated respiratory center and to restore the abdominal muscles to an inactive state at which abdominal relaxation again prevails. Of importance during pelvic surgery is the fact that a similar activation of respiration in the visceral thoracic region may be elicited by compressing the viscera upward against the diaphragm. This compression reflex (Fig 2) manifests itself on the pneumograph by an abrupt shift of the thorax to the position of extreme inspiration as indicated by an abrupt downward shift in the level of the curve. Superimposed on this

FIGURE 2 Thoracic Compression (Visceral) Reflex

The first segment of the chart shows normal respiration with the abdomen opened. The next depressed level of the curve is due to compression of the viscera and fatty mesenteries upward against the diaphragm in obese patients. This opens the thorax to the position of extreme inspiration (downstroke of pen). Sharp, irregular, forced expirations press the viscera downward toward the pelvis. The final high portion of the curve (needle elevated) shows the undesirable degree of depression of respiration with Pentothal necessary to control this forceful reflex in extremely obese patients, abdominal relaxation being restored.

lowered curve are jerky, irregular respiratory efforts. These efforts, which are due to reflex activation of the abdominal muscles as accessory expiratory muscles of respiration, cause expiratory protrusion of the retracted viscera into the pelvis. The compression reflex is activated in the presence of extreme obesity by pressure of the viscera against the diaphragm. It may be one of the most powerful and persistent reflexes in the body, requiring such undesirably large quantities of Pentothal to suppress it as to make the supplemental use of some other agent, such as cyclopropane, or ether, desirable. This compression reflex is not activated in the average pelvic case in nonobese patients.

The reflex activation of respiration in the lumbar visceral zone (autonomic) consists of a minimal increase in the amplitude and rate of respiration. There is no activation of the abdominal accessory muscles of expiration, so that abdominal relaxation is not disturbed. The character of the response is shown in Figure 3, which demonstrates that, after a brief quiet run without trauma, crushing and pulling of the presacral lumbar nerves (superior hypogastric plexus) causes a definite but slight increase in the amplitude and rate of respiration. Procaine injection above the level of trauma in the region of the lumbar plexus obliterates first the stimulus to the rate of respiration and secondly the stimulus to the amplitude of respiration. This minimal respiratory response to trauma in the

FIGURE 3 Lumbar Visceral Reflex

The chart illustrates a normal unstimulated run up to point A. Between A and B an increase in rate and amplitude from traction and squeezing of the presacral nerve plexus (superior hypogastric) occurs. At point B procaine injection above the point of trauma causes an immediate reduction in the rate and a gradual reduction in the amplitude of respiration. At point C after the proximal end of the plexus has been severed a fixed slower rate and a reduced amplitude are established.

lumbar autonomic zone increases the need for additional Pentothal administration very little if any.

Trauma in the area of distribution of the sacral autonomic nerves elicits two characteristic types of respiratory response, both of which are induced by traction on the uterus, which in turn establishes tension in the uterosacral ligaments. The first type of reflex response to traction is inspiratory, and the second is expiratory. The two types of response do not occur simultaneously in the same patient. There is but a momentary response to each movement of traction, in contrast to the prolonged, repetitive types of response to trauma in the other neurologic zones. Figure 4 demonstrates the first type of inspiratory response to traction. Each movement of traction on the uterus—even after all attachments above the cervix have been severed and the vaginal cuff has been completely detached from the cervix anteriorly and laterally so that only the posterior uterosacral region remains intact—is followed by a single prolonged inspiratory effort

accompanied by a single transient, moaning phonation due to a moderate transient laryngospasm. Deep injection of procaine solution in the immediate vicinity of the inferior hypogastric plexus (sacral autonomic) completely obliterates this response to

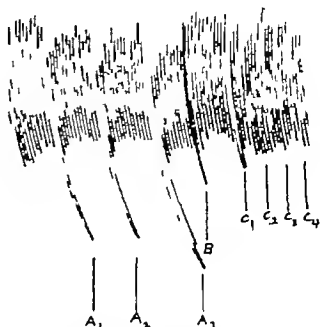

FIGURE 4 Sacral Visceral (Inspiratory) Reflex

Individual tractions on the uterosacral ligaments at points A₁, A₂, and A₃ evoke single prolonged inspiratory responses, associated with reflex moaning laryngeal phonation. At point B (kymograph stopped) a deep presacral injection of procaine (inferior hypogastric plexus) has been made. Subsequently a single minimal response occurs with traction at point C₁ from incomplete procainization, whereas traction at points C₂, C₃, and C₄ shows complete elimination of all inspiratory responses and laryngeal phonation after complete procainization. This reflex is mediated via the sacral autonomic nerves in the uterosacral ligaments. Abdominal relaxation is not disturbed by this reflex since the abdominal muscles are not activated during expiration.

traction. In some cases it was noted that this unique response was elicited only when the tractile effort coincided with the peak of expiration, it did not occur when the traction coincided with the peak of inspiration. In the second type of expiratory response to traction there are brief episodes of expiratory response occurring coincidentally with traction on the uterus (Fig. 5). The response does not outlast the tractile effort and persists for only one to three respiratory cycles. The response could be elicited whether the tractile effort coincided with the peak of inspiration or the peak of expiration. This expiratory response is also obliterated by deep sacral procaine block of the inferior hypogastric plexus, indicating as in the first type of response that it is a reflex mediated through the sacral autonomic plexus of nerves. Furthermore, both types of reflex response were obliterated by procaine infiltration of the uterosacral ligaments, demonstrating that the afferent nerve fibers that conduct activating pain impulses into the sacral plexus traverse these anatomic structures. These sacral reflexes may be a factor in pelvic and low-back pain when the uterosacral ligaments are involved by conditions such as

pelvic inflammatory disease and endometriosis. In the first type of inspiratory response to traction there is no activation of the abdominal expiratory muscles and hence no disturbance of abdominal relaxation. There is consequently no need for increased quantities of Pentothal. In the second type of expiratory response there is a brief tensing of the

tively by the pneumograph and bears out the quantitative observations.

SUMMARY

A report on the use of combined intravenous Pentothal sodium and local nerve block as a method of anesthesia in gynecologic surgery is presented. The safety of the method is attested by the fact that the over-all mortality for the entire group was 0.4 of 1 per cent and that for the major gynecologic procedures was 0.7 of 1 per cent, with no relation between mortality and anesthesia.

Two parallel groups of hysterectomies were done, the first without and the second with procaine field block of the pelvis. There was a 50 per cent reduction in the rate of utilization of Pentothal from 0.006 gm. a minute without field block to 0.003 a minute with the field block. This parallels the 50 per cent reduction in the rate of utilization of Pentothal as reported previously in cholecystectomy by anterior splanchnic block and in radical mastectomy by intercostal nerve block.

The major importance of a previously experienced pregnancy in determining a satisfactory degree of muscular relaxation under Pentothal anesthesia alone is indicated. The supplemental method of rectus muscle block with procaine provides a flaccid paralysis of the muscles routinely, so that surgery may be done in relatively light planes of Pentothal anesthesia that are wholly free from respiratory depression.

Pneumographic tracings demonstrating the characteristic patterns of reflex response of respiration to trauma in the three neurologic fields involved by surgical trauma during pelvic surgery (thoracic, lumbar and sacral) are presented.

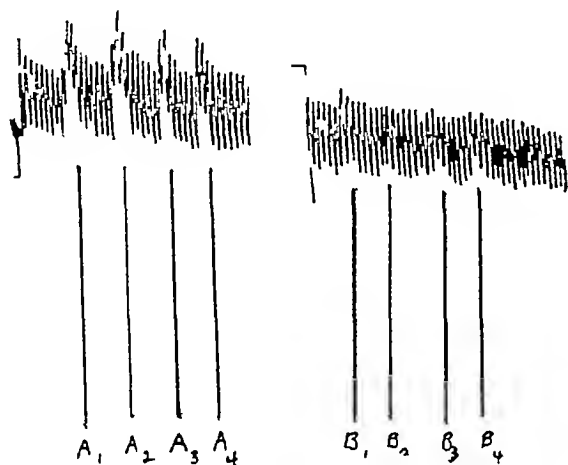

FIGURE 5. Sacral / visceral (Expiratory) Reflex.

At the successive points of elevation of the curves A₁, A₂, A₃ and A₄, which coincided with traction on the uterus, there was moderate tensing of the abdominal muscles during expiration for one to three respiratory cycles. Even though the traction continued, the stimulus disappeared, and the curve returned to its initial level. This slight tensing of the abdominal muscles caused a transient downward crowding of the retracted viscera toward the pelvis. As demonstrated in the second portion of the curve, this reflex is also obliterated by procainization of either the utero-sacral ligaments or the sacral plexus (inferior hypogastric). Traction at B₁, B₂, B₃ and B₄ shows no significant expiratory response. There is never any laryngeal phonation with this expiratory reflex, which is mostly tonic in character.

accessory expiratory muscles of the abdomen with each traction, which in turn causes a slight momentary protrusion of the retracted viscera downward toward the pelvis. This reflex leads to a moderate increase in the rate of administration of Pentothal for its control. However, in both types of response the minimal character of the activation of respiration by surgical trauma in the sacral autonomic as well as in the lumbar region is demonstrated qualita-

BRONCHIECTASIS TREATMENT AND PREVENTION*

THEODORE L. BADGER, M.D.†

BOSTON

BRONCHIECTASIS is protean in its expressions as it is sometimes obscure in its origin. The clinical picture varies in individual patients, but common to the severer cases is a history of harassing, recurrent pulmonary infection, head colds or sinusitis that "goes down into the chest," to remain for weeks with a productive cough, or one of recurrent hemoptyses or repeated attacks of pneumonia. As a rule, severe pulmonary infections date the onset of the symptoms of bronchiectasis. With great clarity patients recall childhood and adult pneumonias, measles and whooping cough, influenza and "croup" as the beginning of the pulmonary trouble. In many cases each succeeding reinfection aggravates the symptoms. Patients with extensive disease may be seriously toxic with fever, abundant sputum, often foul smelling, a poor appetite, inability to gain weight and physical weakness. Psychologically, some of them are problems of adaptation to a life of severe invalidism in a society in which their presence may be offensive because of cough and the bad odor of their secretions. If surgery is unsuitable for them, they become a difficult problem in medical care. It is said that bronchiectasis acquired in infancy (before the age of two) is a highly fatal disease, and Anspach¹ states that all infants die who develop it in their first year of life. Few untreated patients who acquire bronchiectasis before the age of ten live past the age of forty.² But when the disease is acquired after thirty years of age, patients live on, often without the increasing disabilities of emphysema, fibrosis and cough that may accompany chronic pulmonary infections in advancing years. It is true that bronchiectasis is the commonest cause of nontuberculous pulmonary hemorrhage in all ages,³ as well as the most frequent cause of hemorrhage up to the age of twenty.⁴ And it is known that bronchiectasis may be simply the sentinal clinical condition that masks an underlying bronchogenic carcinoma or pulmonary tuberculosis.

This grim picture accounts for much of the aura of pessimism surrounding the medical treatment of bronchiectasis. But this point of view is not entirely justified in reviewing the natural history of this disease. For bronchiectasis may exist with few or no symptoms for many years, and long periods of well-being may be interrupted only by sporadic episodes of bronchitis. The individual constitutional factor of high resistance to infection must

be recognized as important in these cases, just as Perry and King² showed that 38 per cent of their nonsurgical patients had an "excellent living and working capacity." It should be clear that there is no stereotyped relation between the pathologic extent of bronchial dilatations and the severity of clinical symptoms. Some patients with extensive bilateral disease live normal lives with minor limitations of cough and sputum, others with so-called "dry bronchiectasis" may have recurrent hemoptyses or pulmonary hemorrhages, and fetid sputum may accompany relatively little unilobular disease. Such is the experience in the clinic at the Boston City Hospital and in private practice. This knowledge of the satisfactory progress of many cases is not entirely understood, but it is stressed to obviate the prevailing pessimism that surrounds medical care, as well as to present a fuller understanding of the long course of bronchiectasis and to substantiate a better prognosis. In the past there has been too great a tendency to group the medically treated case with the wholly untreated case of bronchiectasis into an unsatisfactory nonsurgical or so-called "medical result." The results of a surgical "cure" may be extraordinarily good, but the benefits of medical care should not be overlooked.

It is of great interest that in the Massachusetts General Hospital series of 400 cases, 59 per cent were unsuitable for surgery for one reason or another.² Alexander¹ also points out that in any large number of patients with bronchiectasis 50 per cent should not have excision surgery. The patients not suitable for surgery are those with too much or too little bronchiectasis, those with limited cardiovascular reserve, those with limited pulmonary reserve because of associated emphysema, those with concurrent disease and those who will not submit to surgery. Furthermore, asymptomatic bronchiectasis does not require excision.⁶ Perry and King² also observe that when surgery has been done, follow-up studies indicate that approximately a third of patients operated on still are in poor or only fair condition, in other words, a third of the operated cases subsequently need medical treatment. In these cases residual disease remains with chronic cough, sputum and often hemoptysis that is not suitable for further surgery. Thus, it appears that about two thirds of all cases of bronchiectasis, with or without surgery, require medical supervision and care.

It is because this large number of patients will always need medical treatment that the following considerations are presented. Although the medical

*Part of a symposium on bronchiectasis presented at the annual meetings of the Massachusetts Medical Society, Boston, May 21, 1947.
†Instructor in medicine, Harvard Medical School; consultant on diseases of the lungs, Veterans Administration.

course may be a difficult, painstaking supervision of details in daily living, a simple practical routine may suffice to maintain excellent health

MEDICAL CARE

The medical management of bronchiectasis is directed toward mechanical drainage, the control of infection, measures to improve the general health

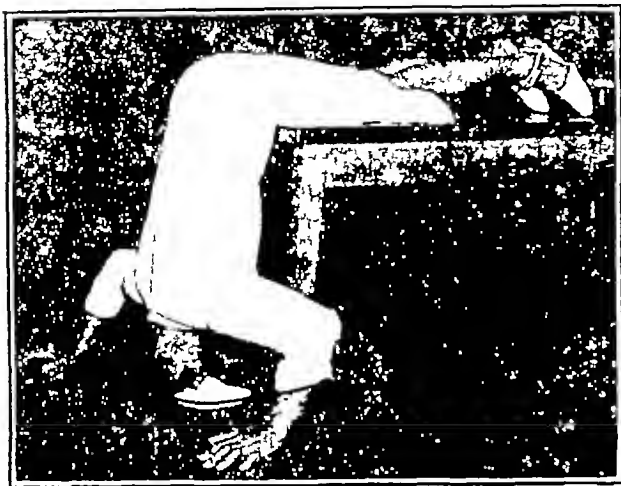

FIGURE 1 *Position of Election for Dependent Vertical Postural Drainage in Basal Bronchiectasis*

of the patient, and (as important as any factor) the prevention of the condition before it occurs

Mechanical Drainage

The Jacksons⁷ compare the putrefaction that gives rise to the foul odor of severe bronchiectasis to the septic tank. Early purulent exudate is often too thick and viscous for expulsion. But with stagnation and bacterial action liquefaction permits expulsion. Medical treatment is aimed at hastening this technique of nature.

Postural drainage thus becomes the most important single mechanical procedure for emptying dependent bronchiectatic cavities of their secretions. The emptying should be as complete as possible and sufficiently frequent to prevent any amount of reaccumulation. It is a treatment that must be carefully studied with each patient. Four details are essential to its proper execution.

The first is position, for postural drainage can best be carried out from a high bed or table with complete vertical dependence of the trunk, with both hands on the floor and with a basin conveniently placed for expectoration (Fig 1). Clumsiness and occasionally weakness and dizziness may accompany the first efforts at treatment, but patients soon accommodate themselves to its use so effectively that it becomes routine. For older patients and obese and dyspneic persons for whom this pro-

cedure is too difficult, it may be arranged by the use of a hinged leaf to a table. Alexander⁸ showed that patients at work who could not find a convenient bed or table for postural drainage could, in the seclusion of a lavatory, substitute the grotesque and somewhat humorous position of flexion at the waist, with the knees slightly bent, the head far down, the buttocks as high as possible and the hands grasped behind the knees (Fig 2). This provides a fairly effective substitute form of postural drainage. Secondly, for the best results in postural drainage, the thinning of stagnant secretions becomes essential for their mechanical removal. Many shotgun expectorants are available, but the most effective are iodides, ordinary steam inhalations, ammonium chloride and creosote. Depressants with

FIGURE 2 *Substitute Position for Drainage of Basal Bronchiectasis When a High Table or Bed Is Not Available, As When at Work*

morphine derivatives should be avoided if possible, since they become habit forming in the chronic course of the disease and reduce expulsion of secretions, facilitating retention in the lung. Thirdly, bronchodilators such as adrenalin, ephedrine, Aminophylline and mucosal vasoconstrictors like Neo-Synephrine inhaled judiciously through a nebulizer with oxygen under pressure, or by a hand-bulb method, may greatly facilitate the loosening of secretions for postural drainage. And fourthly, deep expiratory and very deep inspiratory breathing before and during postural drainage may help the emptying of deep secretions. The frequency of performing postural drainage is a matter of individual trial and error. The timetable may be every two hours, or once a day, but should be often enough to keep the sacculations as free as possible from secretions. There may be long periods when drainage is unnecessary. Constant drainage cannot be carried out. Lying on the opposite side with some elevation of the foot of the bed is in no way as

effective as the vertical dependent position. Many patients, however, who produce nothing while in this position raise abundant quantities of sputum immediately on sitting upright.

An example of the value of regularity in postural drainage is provided by the case of a fifty-seven-year-old man, who was followed sporadically for ten years in the Thoracic Clinic of the Boston City Hospital for bilateral basal saccular and cylindrical bronchiectasis. He returned not long ago for check-up on a recent pneumonia controlled easily with penicillin. He was well and strong, looked ten years younger than his age and had only a morning cough and expectoration. In 1937 this man had first been seen in the Thoracic Clinic for severe recurrent hemoptyses of 30 to 180 cc of red blood off and on for two years, with cough and productive sputum. So extensive was the bronchiectasis in both lower lobes that bilateral lobectomy was advised, but refused. Consequently, the patient was schooled in the art of postural drainage and advised to use it every two hours. In time, it became unnecessary to go into position often, and for several years, with unflinching regularity, he has carried out the postural drainage once daily. Each morning he raises not more than 5 to 10 cc of thin mucopurulent material, rarely coughing again until the next day's postural drainage. The patient states that he has lived and worked without interruption because of illness.

Bronchoscopy remains an important procedure in the handling of bronchiectasis, and a necessary one in cases presented for surgery. Its need is for the removal of unsuspected foreign bodies and for the diagnosis of primary bronchogenic carcinoma, which is too often masked by bronchiectasis. The procedure is useful in segmental location of the disease within the lung and of value in aspiration treatment. Deep, widespread, careful aspiration of bronchiectatic lobes after shrinking of the mucosa occasionally has a place in the mechanical removal of secretions, but its regular routine use has been valueless.

Control of Infection

Chemotherapy in any form has so far provided no cure for bronchiectasis, but its judicious use in conjunction with mechanical drainage can make life bearable for many patients with severe bronchiectasis and can shorten the duration of the acute attacks of bronchitis and pneumonitis in milder cases.⁸⁻¹²

The bacteriology of bronchiectasis in its chronic phase is a composite picture of mouth organisms giving place to predominant types only during intercurrent pneumonias and infections. Both inhalation and intramuscular administration of penicillin have earned their place singly and simultaneously in the medical treatment of this disease. The purpose of inhalation is the direct application of the drug to the bronchial walls and to the secretions of the sacular dilatations. Blood levels

are much lower than those obtained by intramuscular administration. Absorption by the respiratory route alone is not adequate to take care of deep-seated pulmonary suppuration. Penicillin by inhalation should not be expected to reach deep into bronchi obstructed by thick secretions. Therefore, well executed postural drainage should precede the use of penicillin aerosol. If necessary, inhalation or injection of bronchodilators may be used with postural drainage in the first days of acute attacks.

The use of penicillin by whatever route in this chronic disease marked by exacerbations of symptoms must be considered temporary. Its value is dependent on the suppression of sensitive organisms, and its usefulness wears off in two to four weeks. The remission will last until another acute respiratory infection supervenes, unless the fundamental principles of mechanical drainage continue to be carried out regularly and with recognized effectiveness. Dependence on effectiveness of the drug without postural drainage is unwarranted.

At present, studies point toward the usefulness of sulfadiazine in daily doses of 1 gm for many months. Segal¹³ has had success with its use in long-term medical management of bacterial control in bronchiectasis, between brief periodic uses of penicillin. But in the long-term use of sulfadiazine even non-allergic patients must be guarded carefully against sensitivities. The best results with any drug will be in patients with the most sensitive organisms and in those with the best inherent constitutional resistance to respiratory infections. Studies of bacterial flora will help, especially in the difficult case.

Intercurrent infections of virus type, like the common cold, grippe, influenza and virus pneumonias, commonly excite otherwise quiescent bronchiectasis into acute exacerbations. Inhalation of penicillin or sulfadiazine at the beginning of such infections, although known to be ineffective against the virus, has in my experience been valuable in preventing secondary invaders and serious reactivation of existing bronchiectasis.

Sinusitis has a varied influence on the symptomatic course of bronchiectasis. Goodale¹⁴ has shown that there is a high incidence of sinusitis in the late years of bronchiectasis, and the more extensive the bronchiectasis, the more severe the sinus disease. Once sinusitis is acquired he believes that damage to the lungs is increased. At the same time, however, he points out that these patients are more susceptible to respiratory infections. This concept is entirely logical, for spread of sinus infection by the bronchial route is direct, and spread by lymphatic drainage is by the right side of the heart to the lungs. Sinusitis has been quite thoroughly exonerated as an etiologic factor in bronchiectasis. The influence of sinusitis on bronchiectasis and vice versa is often seen by the clearing of infection in either one followed by beneficial effects

upon the other. But sinus disease is closely linked to individual susceptibility to infection, and conservative care of sinusitis with chemotherapy deserves a trial. So too with the mouth, all infections of the teeth and gums need meticulous care.

Improvement of General Health and Hygiene

Patients with bronchiectasis must learn to live with their disease and to make the adjustments that are essential to their well-being. Like the patient with valvular heart disease who must avoid competitive sports and severe exertion, the patient with bronchiectasis must protect himself against respiratory infections and take good care of those that come his way. Good nutrition is important in the control of any chronic infection. Its specificity, however, is hard to define except in the maintenance of normal body weight by a diet high in protein and vitamins in this disease in which nitrogen catabolism is elevated by chronic infection. The prevention of anemias in the presence of infection deserves serious attention. A life well regulated with rest and exercise should be so ordered as to avoid any lasting fatigue. Smoking may aggravate a respiratory mucosa already inflamed with basal infection, especially in patients sensitive to nicotine. Avoidance of exposure to cold and wet and sleeping in warm fresh air, rather than freezing cold drafty rooms, are of value to those who are sensitive to acute respiratory diseases. Change of climate to higher inland areas well away from the Eastern seaboard may contribute to the well-being of patients with more serious disease. These details—each one in itself, perhaps, unimportant—all contribute to build up the general health, which chronic infection tends to break down.

Prevention

Knowledge of the cause and pathogenesis of bronchiectasis has contributed greatly to understanding of its clinical picture. The part played by atelectasis and infection from whatever cause should lay the pattern for prevention. It has been shown that 65 per cent of all cases develop in the first two decades of life² and that bronchiectasis is the leading cause of hemoptysis and pulmonary hemorrhage in that age period.^{3, 4} Thus, two thirds of the problem of prevention is in the hands of those physicians who care for children. Lobar and lobular atelectases lay the foundation for the development of bronchial dilatations.^{1, 15-20} Thick tenacious mucus, in the form of obstructing bronchial plugs, has been shown by Clerf^{21, 22} to produce the clinical and x-ray signs of collapsed lobes. But infection without atelectasis may also cause bronchial dilatation by its destruction of the bronchial wall.²³ Probably, both atelectasis and infection conjointly are responsible etiologic factors.

Prevention thus takes two major directions. The first is early diagnosis of bacterial pneumonias, with

adequate chemotherapy. The second is re-expansion of atelectases that persist after pneumonias and acute respiratory infections, especially in children.

The unresolved pneumonias, the continued or recurrent coughs with low-grade fever and the lasting physical signs that follow acute respiratory disease may mask or may be the signs of remaining atelectasis of small bronchioles or lobules of the lung. Massive collapse is not necessarily present, and it is the smaller pulmonary segments that are revealed only by x-ray study when the acute disease is over. But for more practical purposes, deep-breathing exercises of the affected side—forced expansion of the chest hourly against the pressure of a hand placed over the pneumonic area—may be begun immediately after the acute phase has subsided. This method, described by Harkin²⁴ and used in conjunction with expectorants and postural drainage, may be sufficient to expel obstructing bronchial plugs and re-expand residual atelectases. X-ray evidence of definite collapse that does not clear with these simple measures indicates the need for bronchoscopy for aspiration of the mucous plug.

A further step in the field of prevention of bronchiectasis is the prompt removal of aspirated foreign bodies and of benign endobronchial tumors before permanent bronchial damage has occurred. The early diagnosis of lung abscess, with active chemotherapy and early surgery if necessary, should prevent the bronchiectasis that commonly follows it.

CONCLUSIONS

A prophecy for significant reduction in the incidence of bronchiectasis in the future lies in the experience that the prevention of bronchiectasis will naturally follow the present-day treatment of pneumonias and respiratory infections of bacterial origin, especially in childhood. The medical treatment discussed above is not offered as a substitute for the case of bronchiectasis uniquely suited for excision surgery. It is offered for patients who already have the disease and are not suitable for operation or refuse it. The natural history of bronchiectasis is so varied in its course that the following factors are needed: a careful medical and surgical evaluation in each case, a period of observation when the details of mechanical drainage are studied, a time when the bacteriology and effects of chemotherapy on its control are observed, and a place where the general health and hygiene of the patient are reviewed and measures of prevention against common respiratory diseases are instituted. But especially is there need to weigh the unknown factors of constitutional resistance or susceptibility to respiratory infection when the prognosis of bronchiectasis is evaluated in each case.

ESOPHAGEAL STRICTURE FOLLOWING AGRANULOCYTOSIS DUE TO SULFONAMIDE THERAPY

Report of a Case

BURTON D. BRYAN, M.D.*

FALL RIVER, MASSACHUSETTS

SULFONAMIDE therapy carries with it the threat of depression of the centers of blood formation and agranulocytosis and thus of agranulocytosis angina. Should the process that sets up this angina extend to the esophagus, acute esophagitis results. The patient may survive the acute phases of the disease, only to face marked esophageal stenosis as a result of secondary cicatricial scarring. Investigation of the literature has revealed no reports similar to the following case of esophageal stricture resulting from agranulocytosis caused by sulfonamide therapy.

In November, 1945 a 38-year-old woman was admitted to the hospital with a peritonsillar abscess.

The past history included numerous attacks of cholecystitis and renal-tract infection. Sulfadiazine had been prescribed, except during the last attack which immediately preceded the present illness and for which she had been treated at a Boston clinic with sulfathiazole.

The present illness had begun 8 days previously with a sore throat. A physician prescribed 1 gm. of sulfadiazine every 3 hours. This regime was continued until admission. How ever in spite of this therapy, the patient became rapidly worse.

On admission a peritonsillar abscess was found and opened. Pus exuded from the wound. Ulcerations on the buccal mucosa gradually became fulminating and spread to the lips. The white-cell count was only 1200, all of which appeared to be lymphocytes; no young forms were found. To complicate the situation further, the blood was Rh—.

The temperature rose from 102 on admission to 105°F on the second day and then spiked between 102 and 105°F until the 7th and 8th hospital days, when it rose to 106°F.

Sulfadiazine was stopped on admission and 30,000 units of penicillin intramuscularly every 3 hours was started. The patient was supported with intravenous fluids and transfusions of compatible blood. However her condition grew steadily worse during the first 8 days. The pulse went from 120 to 140 per minute and then to 160 per minute for short periods. The quality became poor. The patient became irrational. Rales appeared in the chest and it was necessary to suction the upper air passages to keep them clear.

Dr. William F. Murphy of Boston who saw the patient in consultation expressed the opinion that the agranulocytosis

was due to the sulfonamides previously administered and that the present therapy, which included liver extract, was correct. He was encouraged by the blood smear on the 9th day, which

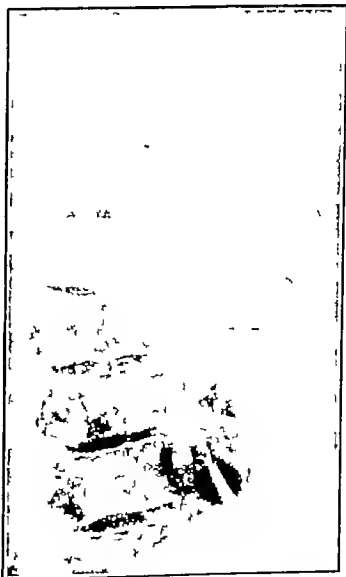

FIGURE 1. Roentgenogram Showing Esophageal Stenosis on May 1, 1946 before Passage of a Bougie

showed a white-cell count of 3000 with young forms indicating bone-marrow activity.

By the 11th day there was slight improvement and after the 14th day rapid clinical recovery. During the last days of

*Otolaryngologist, Truist Hospital.

the hospital stay a soft diet caused pain on swallowing, but at discharge on the 36th hospital day the pain had gone, although slight difficulty in swallowing remained.

At home, the patient at first gained weight and by chewing her food thoroughly swallowed without too much difficulty.

FIGURE 2 Roentgenogram Showing Esophageal Stenosis on September 12, 1946, after Passage of a No 32 Fr Bougie

However, the dysphagia progressed until May, 1946, when she could swallow only fluids or thin gruels. She had lost 10 pounds during the previous 2 months.

A barium study revealed a normal esophagus down to the level of the carina. From that point, the esophagus showed a

long, funnel-like narrowing, where the lumen was gradually reduced to 5 mm, thin barium flowed fairly readily through the involved segment, but thick barium paste met almost complete obstruction (Fig 1).

A size 9-54 Jackson esophagoscope was passed to the level of the carina, above which the lumen and mucosa appeared normal. At this point, the lumen narrowed markedly, and the mucosa was pale and lusterless. The esophagoscope was withdrawn and No 14 and 16 Fr filiform bougies were slowly passed. Moderate resistance was met.

The patient subsequently noticed slight improvement in ability to swallow. She was discharged and has returned at intervals of 2 and 3 weeks for bouginage. The size of the bougie has been slowly increased until a No 34 Fr is now used. She has gained weight and feels well. However, after 2 or 3 weeks, increasing dysphagia slowly returns. Furthermore, bougies larger than a No 34 Fr meet with marked resistance. Figure 2 demonstrates esophageal stenosis after passage of a No 32 Fr bougie.

Dr Richard H Sweet, of Boston, who examined the esophageal x-ray films, stated that after further study this patient might be a good candidate for transthoracic esophagectomy.*

SUMMARY

A case of marked esophageal stenosis following agranulocytosis due to sulfonamide therapy is reported.

It is assumed that the same ulcerative process that caused the severe angina of the mouth caused ulcers in the esophagus and that, after the acute esophagitis had resolved, secondary cicatricial stenosis took place.

Had the nature of the process taking place in the esophagus been appreciated sooner, bouginage at an earlier date might have prevented the resulting stenosis.

A search of the literature has failed to reveal a similar case.

151 Rock Street

*Since this paper was submitted for publication Dr Sweet has successfully performed a transthoracic esophagectomy. The patient now swallows without difficulty. Because of the new elevated position of the stomach large meals cause mild dyspnea, but if small meals are eaten more frequently, no distress is encountered.

THE DOCTOR AND VOCATIONAL REHABILITATION FOR CIVILIANS IN MASSACHUSETTS

HERBERT A. DALLAS*

BOSTON

A OPPORTUNITY for members of the medical profession to take part in the vocational rehabilitation of handicapped civilians is presented to the private practitioner and specialist through a program administered by each state in partnership with the federal government. Recently, a pamphlet entitled *The Doctor and Vocational Rehabilitation for Civilians* was sent to all members of the American Medical Association, with a copy of a letter from Henry H. Kessler, M.D., consultant to the Office of Vocational Rehabilitation, Federal Security Agency, to inform every physician of the new services available for the assistance of handicapped patients. The Division of Vocational Rehabilitation of the Department of Education is the agency in Massachusetts by which this program is administered for the restoration of the earning capacity of the handicapped to enable them to earn their livelihood in competition with the able-bodied. The achievement of this goal for disabled civilians, who outnumber those disabled in war, rests primarily in the hands of the physicians, who are the logical case finders as well as the final purveyors of the necessary medical treatment.

Vocational Rehabilitation was established by the National Rehabilitation Act in 1920, when Congress granted financial aid to the States for disabled civilians. It was established as a public service in the same sense as the school systems, health departments and public libraries to extend vocational training to the physically handicapped. It was not until Public Law 113 was passed by Congress in 1943, amending the National Rehabilitation Act, that medical care could be provided to alleviate a condition, either physical or mental, that constitutes a vocational handicap.

To be eligible for the services of the Division of Vocational Rehabilitation, an applicant must be a resident of Massachusetts and of legal employable age (sixteen years) and must have a physical or mental disability that prevents him from obtaining employment. Any patient whom the physician regards as eligible can be referred to the Division for consideration. A report of the physician's findings and recommendations should accompany the referral.

Successful rehabilitation, which may be a long and complex process, requires the integration of professional skills at every stage. To aid him in working with the patient as a person, the physician

needs a team of skilled workers, including the nurse, medical social worker and occupational and physical therapists, as well as the vocational counselor of the Division, who knows the employment field and the facilities for training for suitable occupations for the handicapped patient. Rehabilitation should begin at the point of diagnosis, when the extent of disability may be estimated and plans formulated for the eventual return of the patient to economic usefulness. To attain this goal, each person should be evaluated from a medical, psychologic and emotional standpoint prior to selecting a vocational objective, since many factors need to be considered in helping a handicapped person select a suitable employment objective.

It is the policy of this program to compensate physicians, clinics and hospitals of the patient's choice for their care of the patient in the same manner in which it compensates the schools and colleges for tuition. A professional advisory committee, which is composed of several physicians, including a member appointed by the Massachusetts Medical Society, and members of allied professions have been appointed to advise the Division concerning physical-restoration policies and procedures. The chairman of the Committee on Rehabilitation of the Massachusetts Medical Society is the member representing the Society on the advisory committee. The professional advisory committee has approved the State plan for providing medical care and a fee schedule prepared by the Committee on Rehabilitation of the Massachusetts Medical Society. The fee schedule approximates Blue Shield fees and is in conformity with fees paid by the federal Bureau of Employees Compensation and the Massachusetts Departments of Public Health and Industrial Accidents. The fee schedule submitted by the Committee on Rehabilitation of the Massachusetts Medical Society was published in the *Journal* in the issue of December 20, 1945. This fee schedule has been approved, in condensed form, by the federal Office of Vocational Rehabilitation. Upon request, the division will gladly supply any physician with detailed information about the schedule.

Applications for vocational rehabilitation for eligible persons should be made to any office of the Division of Rehabilitation as soon as possible after the onset of the disability. Application may be made in person or by mail and by the handicapped person himself or in his behalf by a physician, hospital, medical social worker, employer, insurance company, fraternal or labor organization, friend or relative or

*Director, Division of Vocational Rehabilitation, Massachusetts Department of Education.

by any interested citizen or agency. It is not necessary to use any special form or blank.

The Commonwealth is divided into districts, and a vocational counselor is assigned to a group of communities for work with applicants residing there. The administrative office is located in the Education Building, 200 Newbury Street, Boston, where the Chief Medical Consultant is available on a part-time basis for advice on physical-restoration policies and procedures and for decisions on cases to be accepted for medical and surgical treatment. District offices are located in Boston, Springfield and Lowell, with branch offices in New Bedford, Worcester and Pittsfield. Medical consultants who are attached to each district office review the medical material on each applicant, discuss his limitations for employment with the vocational counselor and decide whether the mental or physical disability is a substantial employment handicap from a medical standpoint. Further diagnostic procedures are recommended by the consultants, when indicated, for which the Division may be financially responsible without investigation of the economic need of the applicant. However, when treatment is advised, financial need for these services must be established.

An applicant may select his family physician — or any physician licensed to practice medicine in Massachusetts — for the general medical examination, which is required for all applicants. This may be paid for by the Division, according to the fee schedule. A serologic test and a urinalysis are essential parts of this examination, which is designed to give full information concerning the person's general physical condition as well as the specific disability for which he is being referred. The opinion of the doctor regarding the occupational limitations is especially important. The report form has recently been revised by the medical consultants to the federal agency and has been simplified as much as possible to save the doctor's time and still include the information necessary. If the general medical examination indicates the need of a specialist's examination, the physician is asked to recommend such a procedure, and the medical consultant of the Division will authorize an examination by a qualified specialist selected by the applicant and the physician.

Every person accepted for vocational rehabilitation by the Division receives counseling and guidance. He may receive vocational training or education in schools, on the job, by correspondence or by tutor or service for placement in the right job. All these services may be given without determination of economic need.

It is necessary, however, to determine economic need for the following services, if they are required to prepare for employment: surgical and medical treatment and psychotherapy, hospitalization, not to exceed ninety days, specialist treatment in any field, prosthetic appliances, including artificial limbs

and hearing aids, physical and occupational therapy, dental treatment, and nursing services, drugs and supplies. Instructional and training supplies, transportation and maintenance if required during rehabilitation are included.

In determining financial need, the Division recognizes that an applicant may have sufficient income to meet all ordinary living expenses but may lack a surplus to meet the cost of medical care. The program of physical-restoration services is designed to help the medically indigent, who often postpone surgery and medical care, necessary as part of a rehabilitation plan, because they are unable to pay for the service.

Eligibility for physical restoration further requires that the disability must be static, in the terms of Public Law 113. This has been interpreted to mean a disease that is relatively stable, slowly progressive or chronic but amenable to treatment. Care for acute illness may not be furnished, and this program cannot be construed to mean a general medical-care program.

The cost of rehabilitation for employment is readily justified as an actual economic gain, as shown by reports issued by the Division of Vocational Rehabilitation and the federal office. The expenses of rehabilitation are nonrecurring expenditures, whereas public assistance to a handicapped person may be a constant expense for years. Statistics show that at the time of application for rehabilitation, about a third of the applicants were not supporting themselves. Most had never worked, and rehabilitation services enabled many who were working to be more advantageously employed.

Rehabilitation through the Division can be made more effective by the collective action and assistance of individuals and organizations. Close co-operation is maintained with physicians, hospitals, schools for the handicapped as well as public and private schools, social agencies and all state departments concerned with the health and welfare of the residents of Massachusetts. The co-operation of individuals or organizations to develop employment opportunities for the handicapped is especially welcome. Teamwork is necessary in working out the details of a rehabilitation program, and most important of all for its success is the co-operation of the handicapped person himself.

The practicing physician's judgment of the physical condition of the client is the basis on which the rehabilitation plan is built. There is no substitute for this, and the support and approval of Massachusetts physicians is needed by the Division of Vocational Rehabilitation, not only in the carrying out of the rehabilitation services but also in the finding of disabled persons who may benefit by this program. A pamphlet outlining the services available may be obtained on application to any of the offices of the Division.

MEDICAL PROGRESS

CUTANEOUS MEDICINE (Concluded)

JOHN G. DOWNING, M.D.*

BOSTON

INFECTIONS

Virus

Extensive herpetic eruptions of the lips may be serious, owing to subsequent scarring causing circumoral constriction. Herpes labialis occurs in 25 to 50 per cent of cases of cerebrospinal meningitis on the fourth or fifth day of the disease. It is probably due to the ever-present virus, being activated by febrile illness.

Toward the close of the nineteenth century a complication of infantile eczema characterized by a so-called "varicelliform eruption" was first described by Kaposi¹⁰⁰ as an acute outbreak of numerous vesicles, partly scattered and partly arranged in groups. The vesicles are as large as lentils and are filled with clear serum, and the majority are umbilicated. The largest number of vesicles are found on already eczematous skin, smaller groups appear on previously intact skin. The patients have a high fever and are extremely restless.

A recent paper of Lane and Herold¹⁰¹ has done much to make secure the position of this disease as a separate entity. Barton and Brunsting¹⁰² also treat the condition as a separate disease. King¹⁰³ considers it a complication of atopic eczema—a conclusion reached through investigation of the herpes simplex virus. Ronchese¹⁰⁴ suggests the vaccinia virus as the responsible agent.

There seem to be four features that characterize the disease: an antecedent skin disease, usually atopic dermatitis^{105, 106}; systemic involvement, shown by lymphadenitis, fever, malaise and edema, lentil-sized, umbilicated vesicopustules, discrete or in groups on a bright erythematous base, and limited almost exclusively to the sites of existing skin disease, which crust and break, new ones appearing for seven to ten days, and very slight scarring.

Wenner¹⁰⁷ has identified the herpes simplex virus in 3 cases by methods that leave no room for doubt. Blattner, Heys and Harrison¹⁰⁸ have proved the herpes simplex virus to be present and have grown it in eggs and mice. Barton and Brunsting¹⁰² list the complications as stiff neck, headache, epigastric pain and incontinence of urine and feces, all of which were seen in their cases, and also hemorrhagic diarrhea, anuria, otitis media, purulent rhinitis, conjunctivitis, tetanic spasticity, corneal ulcer, gan-

grenous slough, abscess and suppurative nodes. The virus of herpes simplex, which may cause encephalitis, has been isolated from the glycerinated brain material in 2 cases of fatal encephalitis.¹⁰⁹

Pregnancy may be complicated by various herpetic eruptions. The most serious type is herpes gestationis, which is characterized by pruritic, vesicular eruptions often mistaken for scabies. Bullous lesions may also occur, so that the eruption is often mistaken for pemphigus.

A report of 144 cases of a newly recognized rickettsial disease, so-called "rickettsialpox," in a housing development in New York merits renewed attention for its value in differential diagnosis. The agent was isolated from mites and was named *Rickettsia akari*.¹¹⁰ The disease is characterized by an abrupt onset of chills, fever, sweats and backache, followed after several days by a rash. About a week prior to the onset of the fever there is an initial lesion, variously described by the patients as a pimple, boil, blind boil or insect bite. The initial lesion is a more or less round, red papule, firm to the touch. The papule enlarges and the center becomes vesiculated. Ultimately it shrinks and dries, and a black eschar forms. In the fully developed state the lesion frequently resembles certain stages of vaccinia. Regional lymph nodes are usually enlarged and sometimes slightly tender to the touch. The initial lesion persists for approximately three weeks and usually leaves a small scar. A rash appeared in all the New York cases, usually at the onset of the fever or a day or two later. In some cases it was first seen on the arms or legs, in others, it appeared on the abdomen, back, chest or face. In 2 cases lesions occurred on the mucous membranes, in 1 on the palate and in 1 on the tip of the tongue. In no case was the rash observed on the palms or soles.¹¹¹

Interest in herpes zoster has been renewed by the suggestion of surgical section of the involved nerve or of several segments to relieve the persistent pain of post-zoster neuralgia. This is required in rare cases, but most patients respond to simpler methods of treatment.

Geniculate zoster (the Ramsay-Hunt syndrome) with involvement of the cranial nerves is interestingly described by Tschassany,¹¹² who localized the lesion by the subjective and objective findings.

A virus may be the etiologic factor in conditions such as Behcet's disease. Ten years ago Behcet

*Professor of dermatology, Tufts College Medical School and Boston University School of Medicine.

established as a clinicopathological entity a recurrent triad of symptoms. Characteristic of this syndrome are recurrent ulcerations of the oral cavity and genitals and repeated attacks of uveitis, which in later stages is associated with hypopyon.¹⁶⁷⁻¹⁶⁹ The eye involvement may precede, coincide with or follow the oral and genital manifestations. The ulcers of the mouth and genitals are small and discrete, either aphtha-like or nodular and necrotic. Thomas¹⁷⁰ describes a case that he thinks is the first to be reported in Great Britain.

Thirty-three cases of erythema bullosum malignans of the pluriorificial type occurred at the Willard Parker Hospital for Contagious Diseases between 1932 and 1946, with a mortality of 18 per cent. The most urgent feature requiring immediate and constant ophthalmologic care was the destructive lesions of the cornea and conjunctivas terminating in grave ocular sequelae—panophthalmitis and blindness. An upper respiratory onset occurred in over half the patients, and vaginal and urethral stenosis in 2 cases. The treatment is symptomatic in this disease, in which a virus is suspected as the causative factor. Penicillin administered in 2 recent cases materially aided recovery.¹⁷¹

In 1922 a "new eruptive fever associated with stomatitis and ophthalmia" was reported by Stevens and Johnson.¹⁷² This disease is characterized by an acute, sometimes fulminating systemic reaction, with fever and prostration, erythematous generalized skin rash and severe stomatitis, followed by sloughing. With occasional exceptions¹⁷³ the conjunctivas are involved. The usual period before resolution of the skin lesions is three weeks.¹⁷⁴ The exact appearance of the lesions varies somewhat in different cases, and Stevens and Johnson even repudiated as inadequate the diagnosis of erythema multiforme.¹⁷⁵ Although this disease has been considered primarily pediatric, approximately a third of the cases reported since 1922 have occurred in patients over fifteen years of age,¹⁷⁶⁻¹⁸⁰ the case reported by Jones et al.¹⁸⁰ having occurred in a fifty-six-year-old woman. A case with an erythematous skin eruption associated with fever, a purulent conjunctivitis, severe stomatitis and balanitis is reported by Patz.¹⁸¹ Corneal ulceration with opacification was the only sequela. The course and clinical picture were almost identical with those in the cases described by Stevens and Johnson.

Bacteria

In children the exanthemas of scarlet fever, measles and rubella are readily recognized owing to age expectancy, but in adults they are frequently mistaken for other diseases. Unless a disease is endemic or epidemic, recognition of an infectious or contagious disease by its cutaneous manifestations alone is difficult. The rose spots of typhus and typhoid fever may be similar. In the former, however, these spots change to petechiae, the so-called

"mulberry rash." Petechiae often have a diagnostic and prognostic value.

Twenty years ago Hurxthal¹⁸² described the skin manifestations of subacute bacterial endocarditis and stated that petechiae are found in 50 per cent of cases, conjunctival lesions are most reliable. Small, red or pinkish, cutaneous macules due to emboli and ranging from 2 to 4 mm in diameter are often found on the inside of the palms and on the fingers, soles and toes. These first blanch on pressure, but later may or may not, they clear, leaving areas of fawn-colored pigmentation. Osler nodes are also present, especially at the tips of the fingers and toes, and consist of tender cutaneous nodes. Other lesions, such as purpura, deep tender erythematous nodules and various skin rashes, have been reported. Embolic plugs or hemorrhages of the retinal vessels are common. Osler nodes or conjunctival lesions may be indicative of bacterial endocarditis.¹⁸²

Jones and Tichy¹⁸³ state that a special search should be made for petechiae, Osler nodes, Janeway lesions, splinter hemorrhages beneath the nails and glossiness of the rim of the skin at the nail bases, indicative of early clubbing of the fingers,¹⁸² splenomegaly and changes in the heart murmur. They report 9 cases in which penicillin sterilized the blood in 7.

In the last few years there has been an increase in the number of cases of anthrax in Massachusetts, therefore, physicians should be on the alert for early diagnosis and the rapid institution of penicillin, which is apparently of great value in the control of this disease. From 1940 to 1945 there were 21 cases, with 7 deaths—a mortality of 33 per cent.¹⁸⁴ Furthermore, it appears that the majority of deaths can be avoided if the disease is recognized at an early date and penicillin therapy is immediately instituted.¹⁸⁴⁻¹⁸⁶

A report of 25 cases by Ellingson et al.,¹⁸⁷ with uneventful recovery, recommends the use of penicillin. Their description of the initial lesion is well worth repeating. The earliest visible sign is a small, red macule that becomes elevated to form a firm, red papule. Within a few hours there appears a central vesicle filled with clear or opalescent fluid in which organisms can be demonstrated by smears and cultures. The vesicle may rupture early, leaving a small ulcer or may enlarge by direct extension or by development of a ring of satellite vesicles. A zone of deep-red indurated tissue 2 to 3 mm wide surrounds the vesicles and in turn is surrounded by a zone of erythema 5 to 20 mm wide, fading toward the periphery. Edema about the lesion may be present. A striking feature of the infection is the absence of pain in the lesion itself, which is in sharp contrast to abscesses caused by the common pyogenic organisms. Enlarged regional lymph nodes, however, may be acutely tender during the development of the anthrax lesion.

Pseudomonas aeruginosa infection may be accompanied by various cutaneous eruptions. Stanley¹⁵⁵ states that prominent among the signs of pyocyanous sepsis are skin lesions that begin as macules or vesicles and later become bullous or often pustular. When the surface epithelium is denuded from the lesions and the center sloughs out, a characteristic ulcerated gangrenous area is produced. This was first described by Barker¹⁵⁶ in 1897 and was later named "ecthyma gangrenosum" by Hitschmann and Kreibich.¹⁵⁷ Detailed descriptions of ecthyma of this type were given by Fraenkel¹⁵⁸ in his classic paper written in 1917. It is most frequently encountered in the anogenital region, and also in the axillae, the inner aspects of the thighs and the abdomen, particularly in children. The organism is easily cultured in abundance from these areas of gangrenous skin. The necrosis may penetrate through the skin and subcutaneous tissue to the underlying muscle. Other lesions of the skin seen during the course of bacteremia include the roseola occurring in cases of so-called "Shanghai fever" described by Doid.^{159,160} Erythema nodosum,^{161,162} erythema multiforme and butterfly lesions of the face¹⁶³ resembling lupus erythematosus have also been described during the course of systemic infections with *Ps. aeruginosa*.¹⁶⁴

Stanley believes that the characteristic lesions are ulcerating gangrenous areas on the skin (ecthyma gangrenosum), particularly in the perianal and axillary regions, which were exhibited in 3 of his cases. One of them showed an acute exacerbation of chronic disseminated lupus erythematosus. At the time I saw this patient he had a superimposed eruption resembling an erythema multiforme bullousum of the Stevens-Johnson type.

In treatment the sulfonamides and streptomycin are the agents of choice. A most important point emphasized in Stanley's paper is his statement that sepsis and other serious infections due to this organism are definitely rare. However, because of the widespread use of penicillin, which efficiently removes gram-positive organisms but apparently promotes uninhibited growth of this and other gram-negative bacilli, the incidence of such important infections seems to be increasing.¹⁶⁷

Illness due to *Brucella melitensis* infection may be associated with a rash, nosebleed, glandular swellings and nasal ulcerations. The rash, macular in character, resembles that seen in streptococcal septicemia, the glandular swellings may simulate those of Hodgkin's disease. In a report of 20 cases in Iowa, Jordan and Borts¹⁶⁸ state that the illness was characterized by fever, chills or chilliness, sweating, weakness, loss of weight, headache, muscular pains and leg pains. Although the course was mild in several cases, infection was generally severer than that caused by *Br. abortus*.

Meningococcal meningitis, also known as spotted fever or cerebrospinal fever, is apparently more

prevalent during wartime than at other times. Recognition of the rash is extremely helpful.

Osborne et al.¹⁶⁹ give a clear description of the evolution of the exanthema. In 59 cases (82 per cent) a rash was observed on admission. The skin eruption was purpuric, resembling the so-called "fleabite." These petechial hemorrhages occurred early in the course of the disease and in many cases multiplied rapidly within a short time on the arms and legs, especially about the ankles. Characteristic petechial hemorrhages occurred in the mucous membranes of the mouth and eyes and also on the palms and soles. This fact was helpful in diagnosing the disease in Negroes, whose skin is lighter on the palms and soles than on the rest of the body, making the eruption easy to detect. The organisms can be cultured from these spots and can also be directly visualized by the technic outlined by Tompkins.¹⁷⁰ There has been some speculation why the meningococcus has a predilection for the skin and—in the Waterhouse-Friderichsen syndrome—the adrenal glands. Sacks¹⁷¹ thinks that the meningococcus has an ectodermal tropism that accounts for this. The Waterhouse-Friderichsen syndrome is characterized by the fulminating onset of a petechial or purpuric skin eruption, a peculiar dyspnea and cyanosis and profound peripheral circulatory collapse.^{172,173}

In the last few years the Waterhouse-Friderichsen syndrome has been reported in adults. Formerly it was thought that the disease was limited to children between the ages of two months and two years, occurring rarely in patients over nine years of age. Until February, 1943, there were only 103 cases reported in the literature, and among these only 3 patients recovered. Peabody¹⁷⁴ reports a recovery in an adult who suffered from such enlargement of the petechial spots that she developed deep pressure sores. Two reports stress the value of adrenocortical hormone in treatment.^{175,176}

Hill and Kinney¹⁷⁷ present an excellent clinical and pathological study of the cutaneous lesions in acute meningococcemia based on 5 cases. The presence of a skin rash has always been recognized as one of the earliest and most reliable clinical signs in meningococcemia, a fact that has led clinicians in the past to employ such titles as "malignant purpuric fever," "petechial fever," "black fever" and "spotted fever" for these infections. Concomitantly with the stage of bacteremia, or at various intervals thereafter, the meningococci metastasized to the skin, eyes, joints, heart, adrenal glands or meninges, producing various clinical syndromes. The onset and course varied widely, and the cutaneous patterns included erythematous macules, papules, nodules, vesicles and petechial and purpuric lesions. In some of Hill and Kinney's cases lesions similar to those of erythema nodosum appeared on the lower extremities and were indistinguishable from the type encountered in other

diseases In none of these cases was purpura found alone, but in every case in which it occurred it was associated with petechiae Necrosis and sloughing of purpuric lesions and gangrene of the extremities occurred in 2 patients who recovered

The sequence of events in the pathogenesis of the lesions is the localization of the meningococci in the endothelium, followed by endothelial damage and inflammation of the vessel walls, with resultant necrosis and thrombosis These changes, by permitting the extravasation of red cells, account for the hemorrhagic cutaneous lesions In all cases studied in which the skin manifestations were severe, thrombi were a striking and invariable finding They were composed largely of platelets that were attracted to the damaged endothelial linings In 2 cases in which purpura was a striking feature, the blood platelets were greatly reduced Thrombocytopenia is known to occur in many of the severe febrile illnesses, such as septicemia, typhoid fever, typhus fever, scarlet fever and miliary tuberculosis, and it is not unlikely that the fever is also a factor in the reduction of the platelets in this group of cases Vascular lesions were not restricted to the skin Petechiae and hemorrhagic manifestations were found over the serous surfaces and in the mediastinum, epicardium, endocardium, lungs, liver, kidneys, adrenal glands, intestines and spleen The vascular lesions were similar to those in the skin In other words, the skin lesions are but one manifestation of a generalized pathologic process²⁰⁶

Tuberculosis of the skin is fortunately rare in this part of the country Because of the frequency of pulmonary tuberculosis, however, internists are always on the lookout for the cutaneous manifestations Floyd et al²⁰⁷ conducted interesting experiments by superimposing cutaneous tuberculosis in the guinea pig with pulmonary tuberculosis They discovered that it had a distinctly modifying effect on the disease in the lung through the response of the liver to infection This study was based on clinical work done on the subject of immunity or resistance to phthisis resulting from accidental or deliberate involvement of the epidermis with the tubercle bacillus Among certain observers it has long been an axiom that whenever lupus is present pulmonary tuberculosis rarely occurs subsequently, when it was acquired in a case of pre-existing pulmonary tuberculosis, the course of the disease was materially modified²⁰⁷

A recent classification by Cipollaro²⁰⁸ of the cutaneous lesions found in tuberculosis divides these manifestations into a localized tuberculosis and hematogenous types Among the latter he includes sarcoids The difference in clinical and histologic characteristics can be accounted for by the differences in susceptibility, allergy, virulence of organisms, environmental factors and the like Whether sarcoid should be included under tuberculosis is questionable The etiology and pathogenesis of

sarcoid are not known, and its relation to tuberculosis is not established Frequently these patients are admitted to sanatoriums or exposed to tuberculosis and in this way acquire the disease

Fungi

Smith²⁰⁹ presents an excellent review of fungous infections encountered in general hospital practice—I might add, provided the hospital has a trained mycologist His illustrations are remarkable He discusses the deep mycoses, including histoplasmosis, which has caught the imagination of the medical world Darling's²¹⁰ original cases were characterized by fever, emaciation, anemia, leukopenia, splenomegaly and hepatomegaly More than 50 cases of histoplasmosis have been recorded in the literature, and Schlumberger and Service²¹¹ report a case with autopsy in a nine-and-a-half-week-old baby Thomas and Mitchell²¹² report a case presenting on first impression a syndrome resembling acute adrenocortical insufficiency and later that of a generalized fungous infection, presumably blastomycosis, that was demonstrated ante mortem by material obtained from biopsy to be one of histoplasmosis The patient presented extensive and generalized embolic cutaneous papular lesions

SARCOIDOSIS

In recent years internists, roentgenologists and pathologists have become deeply interested in such entities as disseminated lupus erythematosus, scleroderma, dermatomyositis and polyarteritis nodosa Although clinically they are distinct, attempts have been made to establish a common pathological denominator²¹³ The first three are definite cutaneous diseases with a characteristic dermatologic pattern Sclerodermal changes of the heart and lungs evidenced by roentgen-ray examination and autopsy are reported²¹⁴ A pathologist stated that he could diagnose scleroderma from a section of the heart, but admitted that a sclerosed cutaneous patch might be confirmatory

Apparently, no such cutaneous confirmation is necessary for disseminated lupus erythematosus or sarcoidosis To students of sarcoidosis the testimony on questionable cases of industrial pneumonitis is interesting but confusing The review of Higgins²¹⁵ is worthy of study In an article on pulmonary sarcoidosis he reports that in four years as an industrial physician he had met with 35 cases, with 3 deaths The first and most noticeable symptom was shortness of breath, cyanosis and clubbing of the fingers and toes might or might not be present Skin lesions occurring on the fingers, the front of the thighs and the shins were noted in 5 cases These lesions were similar to papulonecrotic tuberculids By microscopical examination they were diagnosed as typical sarcoids X-ray films were suggestive of silicosis Those of the chest showed a diffuse granularity and nodulation throughout the entire

lung fields. There was no enlargement of the lymph nodes. Bacteriologic study revealed acid-fast bacteria in 8 or 10 cases.

All but 2 of the 35 patients had been engaged in the manufacture of fluorescent mercury-vapor lamps.

According to Higgins the disease does not fit in exactly with the usual conception of Boeck's sarcoid, in which most patients recover. There is considerable evidence that one is dealing with an infection. In the first place, the lesion is similar in nature to tuberculosis; secondly, the disease appears three or four years after the last exposure; lastly, it was possible to identify the same bacterium in several cases, although its pathogenicity has not yet been proved. The possibility of a carrier arises.

The phosphors in most general use were zinc beryllium manganese silicate, magnesium tungstate, magnesium silicate, zinc orthosilicate (willcamite), cadmium borate and lead fluoride. These powders were processed in a plant of the company in another state, where 2 cases of sarcoidosis were found. One occurred two years after exposure to fluorescent powder. Most attention among the phosphors has been directed toward zinc beryllium manganese silicate and especially to its beryllium component. It is made by mixing of beryllium oxide, manganese oxide, zinc oxide and silicic acid. About the time the first of the sarcoidosis cases were seen there were 5 definite cases of acute chemical pneumonitis in employees who had been using zinc beryllium manganese silicate, but not in the plants where the patients mentioned above worked. These persons had had considerable exposure to the dust of this phosphor.

At about the same time there were reports of a number of cases of severe acute chemical pneumonitis in plants where beryllium processing was being done. The evidence in these cases indicates that the pneumonitis was due not to beryllium but to hydrofluoric acid or sulfur trioxide, which were released into the atmosphere during processing. This acute pneumonitis is clinically and roentgenologically a distinctly different entity from sarcoid. Chemical analysis of the lungs of the patients who had died did show some beryllium present.

In summary, Higgins²¹ states

It may be said that there is considerable circumstantial evidence that beryllium is the responsible agent in the causation of sarcoidosis by reason of the association of sarcoid cases in industries using beryllium. However there is still lacking proof that beryllium or its compounds will cause lesions similar to the sarcoid lesions found in the 35 patients described. The prolonged waiting period is not in keeping with the usual behavior of the acute phases of chemical poisoning.

Beryllium poisoning, a recognized entity, is an industrial disease that demands attention because of the loss of manpower and the fatalities incident

to increased production in the beryllium industry. During the last four years 170 cases of poisoning were seen among workers in three plants producing beryllium and its compounds and alloys. The manifestations included dermatitis, chronic skin ulcer and inflammatory changes in the respiratory tract and skin and respiratory changes, occurring concurrently or singly. The severest manifestation was diffuse pneumonitis, which caused the death of 5 patients. Experiments conducted by Hyalop and his associates²² showed that several beryllium compounds are toxic to animals. Both pneumonitis and dermatitis were produced experimentally.

Marradi Fabroni²³ coined the term "berylliosis" for this pathologic condition. The ulcers occur on the exposed parts, particularly the forearms and hands, and are discrete and as a rule single. They cause little distress unless they become infected or are located near a joint and thus subjected to the trauma of motion. Treatment comprises early incision of the papule and curettage of the fibrous base. This center consists of caseous material within which the beryllium crystal can usually be identified. Healing does not take place until the embedded crystal is eliminated.²⁴

Harrell²⁵ gives a clear description of generalized sarcoidosis, but the dermatologic picture varies from that of Boeck,²⁶ who describes a symmetrical eruption consisting of nodules on the head and the extensor surfaces of the skin. They ranged in size from a hemp seed to a bean, and the larger lesions had irregular contours. The lesions involved the skin and were movable with it. At first bright red, they became darker and finally assumed a yellowish or brown color. Slight scaling occurred in the older lesions. There was an increase of lymph nodes and leukocytes.²⁷ Harrell states that the clinical picture is one of a generalized disease that is most easily recognized in the skin and lymph nodes. The symptoms are those recognized in any chronic disease of low virulence and are not specific. Lesions are found by x-ray examination in the lung fields in most cases. These are usually of three types: peribronchial fibrosis or thickening, usually extending downward symmetrically into the lower lobes, symmetrical infiltration in the midlung fields, sparing the apices, and areas resembling miliary tuberculosis with a fine marbled or reticulated appearance. Eosinophils are usually present at some time and may reach 15 to 30 per cent.²⁸ Another type of x-ray appearance is that of diffuse and confluent infiltrations, which may represent a transition from other forms of sarcoidosis and may easily simulate, if not actually develop into, tuberculosis.²⁹

Sarcoidosis can be fatal. Nickerson³⁰ reports that in 6 cases in which autopsies were made, the typical histologic picture of sarcoid was found in the viscera. In 1 case the patient undoubtedly died of sarcoid in a fulminating form. The other cases were examples of incidental sarcoid, the patients dying of

some major disease Nickerson reported lesions in the myocardium, endocardium, pancreas, testis and vertebral and femoral marrow for the first time. A varying amount of collagen was noted in each case. It was minimal in the case in which death was apparently due to the disease, and it is suggested that an increase in the amount of collagen indicates a healing reaction.

On the theory that sarcoid, like lymphogranuloma inguinale, is a virus and that, as with the latter, an antigen could be prepared from infected material for diagnostic use, the following work was done by Williams and Nickerson.²²³ A sarcoid lesion of the skin, 2 cm in diameter, was removed. A portion of the tissue was taken for microscopical study, and the remainder was ground with the aid of sterile sand. To this, physiologic saline solution was added in a volume equal to six times that of tissue. This preparation was then sterilized by heating to 60°C for two hours on two consecutive days. Aerobic and anaerobic cultures were negative at the end of forty-eight hours. In each of the following cases stained sections and animals inoculated with the tissue removed were negative for tuberculosis. The patients showed no evidence of tuberculous infection on clinical examination, cutaneous tests or x-ray examination. The authors summarized their work by stating that 4 cases with clinical and pathological evidence of sarcoid gave skin reactions following the intradermal injection of an antigen made from a sarcoid lesion of the skin. Four normal subjects gave no such reaction. The results suggested that sarcoid is a virus disease and that it is possible to prepare a diagnostic antigen.

Several years later Kveim,²²⁴ unaware of the report of Williams and Nickerson, announced the Kveim reaction for Boeck's sarcoid. After Kveim's first account of a new and specific cutaneous reaction for this disease, further investigations were carried on by Danbolt²²⁵ and by others in the Scandinavian countries. Investigations indicate that the Kveim reaction is an allergic cutaneous one specific for Boeck's sarcoid. A test was made on 104 subjects, 36 of whom had Boeck's sarcoid. A positive Kveim reaction appeared in most patients in the course of the two first weeks after the antigen had been injected. A positive reaction as a rule remains positive for many months. Whereas Kveim's reaction was positive in 34 of 36 cases of definite Boeck's sarcoid, it was negative in all 64 cases that showed no symptoms of this disease. A positive Kveim reaction is a valuable support to the diagnosis of Boeck's sarcoid.^{224, 225}

Pautrier²²⁶ proposed the name of "disease of Besnier-Boeck-Schaumann" to designate a benign and chronic disease, perhaps tuberculous, which reveals itself in cutaneous, ocular, respiratory, lymphatic and osseous manifestations. He associated with the disease of Besnier-Boeck-Schaumann an affection known to ophthalmologists as the

syndrome of Heerfordt.^{226, 227} It consists of endochoroiditis associated with bilateral parotitis, peripheral facial paralysis, recurrent paralysis and often cutaneous manifestations. Lastly, some cases of granular conjunctivitis of Parinaud are undoubtedly associated with Besnier-Boeck-Schaumann disease.²²⁸ This disease, extremely variable in its clinical forms and in its evolutionary methods, usually manifests itself by persistent but not pronounced signs, reaching the eyes, the respiratory apparatus, the skeleton, the lymphoid organs, several glands, such as the parotids, and the spleen, liver and kidneys. But the favorite site is the skin, where it reveals itself by several lesions belonging to the groups of sarcoids.²²⁹⁻²³¹

Longcope^{232, 233} reported that in 11 of his 30 cases of sarcoid eosinophils comprised 6 to 35 per cent of the leukocyte count. During the active phase of the disease the sedimentation rate was sometimes elevated. A noticeable alteration of the plasma proteins was observed, there was an unusual increase in the globulin fraction, often resulting in a definite elevation of the total plasma proteins, even though plasma albumin showed normal or subnormal values.

A review of the literature on sarcoidosis for the last three years reveals no new developments or theories concerning its etiology or treatment. In April, 1944, Reisner²³⁴ reviewed 35 cases. Thirty of these patients were Negroes. The age distribution was eight to over forty years. A study of 15 cases by Thomas²³⁵ in 1943 revealed similar findings. Twelve patients were Negroes, and 13 were females. In all cases there was involvement of several organs, including the skin, lymph nodes, lungs, spleen and liver. The period of observation varied between one and seven years.

Dermatologists have long recognized the systemic manifestations of sarcoid. They realize that the sum total of clinical and pathological findings will determine the diagnosis, not a single finding such as that provided by x-ray study or biopsy. An interesting discussion on chronic granulomas shows the difficulty of diagnosing these conditions without extensive laboratory studies.²³⁶ Included is a case report of a sixty-five-year-old man originally presenting an eruption so nondescript that a dermatologist made a diagnosis of scabies. Later, the patient showed definite nodular lesions on the lower legs. These progressed to pustulation and ulceration, with systemic disturbances that resulted in a fatal ending. The final anatomic diagnosis was tuberculosis of the skin, lungs, liver and spleen.

LUPUS ERYTHEMATOSUS

Over a hundred years ago, in 1841, Cazenave studied an entity previously described by Bielt and gave it the name "lupus erythematosus." Appearing usually on the face, the red elevated, well defined, scaly and atrophic patches of the discoid type of lupus erythematosus are disfiguring

This is especially true in the late stage, owing to atrophy, dirty scaling, stippling and telangiectasia. The disease arouses little interest in the physician because of lack of systemic manifestations. One might believe it to be entirely distinct from disseminated lupus erythematosus if stimulation from sunlight or irritating local or intravenous therapy, such as that with gold, did not frequently transform the local lupus erythematosus to a disseminated type with vascular and nephritic disturbances.

Acute lupus erythematosus disseminatus is a definite clinical entity, with erythematous patches on the face, hands, toes and frequently other areas of the skin. Occasionally, a multiform eruption with bullae, vesicles, purpura and generalized telangiectasia appears. The first attack may be mild, but there are usually a septic temperature, pains in the joints and muscles, lymph-node enlargement, gastrointestinal disturbances and prostration. Anemia, leukopenia and albuminuria are frequent complications. The Libman-Sacks syndrome presents a symptom complex of a septic fever, arthritis, polyserositis, leukopenia, increased globulin, renal disease and verrucous endocarditis. The cutaneous lesions are superficial and vascular. Most cases occur among young women, although an occasional man is affected.

Dine and Wilson²⁷ report a case of disseminated lupus erythematosus in a man with a clinical course of seventeen months. Autopsy revealed thickened serous surfaces, small endocardial vegetations of the Libman-Sacks type and collagenic changes throughout the body involving blood vessels, muscles, serous membranes and the endocardium. Kidney sections showed "hyaline thrombi" with a few "wire-loop" lesions of the glomeruli.

Overexposure to sunlight or ultraviolet radiation preceded the onset in a few of my patients. Other cases have followed a focal infection or an attempt to remove one, such as tonsillectomy or the extraction of an infected tooth. Fox²⁸ suggests allergy as a factor, after citing a case following the injection of horse serum.

In this country little or no etiologic significance is attributed to the rare association of this disease with tuberculosis, but some European observers still adhere to the relation between these two conditions. The diagnosis of Libman-Sacks syndrome without cutaneous manifestations is becoming too popular. Without an erythematous eruption one should be careful in making a diagnosis of lupus erythematosus disseminatus.

I am inclined to agree with Wesselhoef and Weinstein²⁹ in rejecting the Dicks' resurrection of the term "scarlatinae sine eruptione" for lupus erythematosus. Without the rash there is no scarlet fever, even though the patient is infected with a streptococcus that is causing a rash in other patients. To include all infections of the toxin-producing streptococci as scarlet fever is a misuse of the term,

since the resistance of the host is an equally important factor.

In a patient whose condition had been wrongly diagnosed as lupus erythematosus owing to x-ray findings, without an eruption, after two weeks' hospitalization without infectious precautions, a diagnosis of tuberculosis was finally made after a sputum examination showed numerous tubercle bacilli.

An interesting discussion on the diagnosis of lupus erythematosus disseminatus in a nine-year-old Negro admitted to a hospital because of cervical and axillary lymphadenopathy, but no eruption, has been presented.³⁰ The pathologist was unable to refute this diagnosis at autopsy. Klemperec³¹ states that this disease rarely occurs in children. The patient under discussion had a white-cell count of 22,000.

The pathology of acute disseminated lupus erythematosus has been a subject of controversy. Klemperec et al.³² believe that the thesis formerly advanced — that lupus is fundamentally a diffuse vascular disease³³ — is no longer tenable. They present evidence that the basic pathological lesion is a characteristic type of focal connective-tissue degeneration, with all elements taking part in the reaction. Inflammatory reaction, although variable, is nonspecific in type and relatively inconspicuous, and in their words "the alterative phase of the process is far out of proportion to the exudative."³⁴

SCLEROSSES

O'Leary³⁵ classified the dermatoscleroses as a group of diseases that have certain features in common and for that very reason present difficulties in diagnoses. These include scleroderma, scleredema adultorum, acrosclerosis and dermatomyositis. A diffuse collagen disturbance has been suggested as a basis for the resemblance of certain of these diseases to each other. They resemble each other because of the solid edema and sclerosis of the skin.

In scleroderma death is due to diffuse involvement of the viscera. Lindsay et al.³⁶ describe the lesions of the esophagus. In the early stages there is inability to swallow more than a few mouthfuls of liquid, especially while the patient is lying down, a sense of fullness behind the sternum and a burning sensation an hour after eating that is worse when the patient is lying down at night. Fluoroscopy shows a localized narrowing of the esophagus 10 to 12 cm. above the level of the diaphragm, measuring 5 to 8 cm. in length. Dostrovsky³⁷ reports 3 cases of progressive scleroderma, all presenting acrosclerotic symptoms. Varying degrees of roentgenologically identified lesions of the lungs of a sclerotic nature are described. In 2 of the cases, fibrous and cystic changes of the lungs of a sclerodermal nature were found at autopsy.

Acrosclerosis is characterized by hardening of the skin and vasospasm of the extremities. The course is fairly benign, the prognosis regarding life and physical activity is better than that in scleroderma.

Scleredema adultorum follows an acute respiratory-tract infection, with edema of the face or upper part of the chest. The disease heals spontaneously. Vallee²⁴⁶ reports 4 interesting cases following febrile diseases. He shows that scleredema adultorum is found in children and adolescents and that it is a systemic disease, characterized by firm, nonpitting edema affecting usually the face, neck, scalp, conjunctivas, thorax, occasionally the arms and, more rarely, the legs, it spares the hands and feet. Pleural effusions, pericardial effusions and hydrarthroses also occur, the former being localized. The electrocardiogram shows low voltage of the QRS complexes. When the disease involves the face differentiation from dermatomyositis is difficult. Muscle pain, fever, a high sedimentation rate and the widespread erythematous skin lesions occasionally seen in dermatomyositis, as well as the weakness and atrophy that are constant features of the latter disease, are not encountered in scleredema.²⁴⁶

In dermatomyositis the muscles of the shoulder girdle, neck and arms are the most vulnerable of the entire body once the disease has started. Jager and Grossman²⁴⁷ believe that in general the histologic changes in the muscle are nonspecific for dermatomyositis. Keil^{248, 249} has described what he calls the dermatomyositic facies, which he regards as consisting of two elements: definitely swollen eyelids with narrowing of either one or both lid spaces, together with a degree of edematous involvement of the adjacent portions of the cheeks and nose, and a background of faint, rosy or pale-blue skin (some call it wine-colored), the net effect is to create a sort of heliotropic bloating of the face resembling the earlier stages of cadaveric decomposition. Little is known of the exciting agent of dermatomyositis. At the present time it is prudent to accept the broad hypothesis that the various manifestations of this disease are caused by various bacterial factors.²⁵⁰

Periarteritis nodosa is a usually fatal disease of alleged infectious etiology, involving the smaller arteries. Various types of subcutaneous nodules and cutaneous lesions are seen in about 40 per cent of cases. Cutaneous lesions vary from purpura and petechial hemorrhages to areas of necrosis. The veins are involved in a lesser degree. The pathological picture presents a necrotizing inflammation of the lining of the arteries with a pleomorphic infiltrate and resulting injury to the wall of the vessel. It is seen at all ages, even in infancy,²⁵¹ more frequently among males. Treatment has been of little avail. The association with allergic conditions was discussed above in the section on allergy.

Grant²⁵² reports 7 cases in detail. He agrees with Leishman²⁵³ that the rarity of the diagnosis must

be due at least in part to unfamiliarity with the disease. Many of the cases present a complex combination or succession of symptoms that sooner or later suggests the diagnosis. Grant lists his own experiences and gives a review of the majority of previously published cases, which number about 350. The pathology was well described in 1928 by Gruber,²⁵⁴ and little has been added since. The various stages present in a single case agree with the clinical evidence that the lesions tend to occur in crops in the course of the disease, which may last for weeks, months or years. Since only short stretches of the affected vessels are attached, Grant emphasizes the necessity of examining excised tissue in serial sections. A characteristic of the disease is a changing clinical picture, fresh symptoms develop and older ones subside, often to recur, so that numerous diagnoses are made before the nature of the disease is recognized.

Leukocytosis may be extreme, with white-cell counts of 40,000 to 60,000. Rarely is there leukopenia. Eosinophilia is present in over 30 per cent of cases in which a differential count has been recorded, and the count may reach high figures—70 per cent in Strong's²⁵⁵ case. The evidence suggests that periarteritis nodosa is much less rare than is generally believed, that it is not necessarily or even usually fatal and that it can be recognized at the bedside in a considerable proportion of cases.²⁵⁵

TREATMENT

Since the close of the recent war many remarkable advances in therapy have been announced. Streptomycin has been of definite value in tularemia and other serious diseases. O'Leary²⁵⁶ states that although not the ideal agent for the treatment of cutaneous tuberculosis and tuberculids, it offers considerable promise because of its efficacy in guinea pigs inoculated with tuberculosis and because of the varying degrees of improvement in human beings. The therapeutic trials should be continued, and more should be done to stimulate laboratory investigations for a therapeutic agent that will have a more intense specific action against tubercle bacilli in human beings. New antibiotics, such as dihydrostreptomycin, a more stable derivative of streptomycin, and erythrin, extracted from the erythrocytes of rabbits, have been announced.

Radioactive isotopes and the nitrogen mustards have been introduced as agents of promise in therapy of diseases of the lymphoma group.²⁵⁷ They are dangerous remedies, but in my opinion the relief—physical and symptomatic—of the cutaneous manifestations of these maladies outweighs the dangers of therapy. As yet evidence has not been obtained of any therapeutic effect by radioactive phosphorus (P32) on mycosis fungoides, xanthomatosis, melanoma, Ewing tumor, carcinoma of the breast or gall bladder or monocytic leukemia.²⁵⁸ Radioactive phosphorus may be used externally for the treatment

of chronic lesions or growths " Salutory results have been obtained with nitrogen mustard therapy in Hodgkin's disease, lymphosarcoma and chronic leukemia, with dramatic improvement observed in the first two disorders " "

Intravenous injections of ether have been used for pruritus and for relief of the painful ischemia in diabetes, Buerger's disease and Raynaud's disease. One may visualize many new possibilities, including less dangerous derivatives of nitrogen mustard gas and better control of radioactive phosphorus, in the treatment of nonfatal diseases such as atopic dermatitis.

Numerous authors have reported excellent results in the use of Benadryl and Pyribenzamine in various cutaneous eruptions, with stress on the results in urticaria.²¹⁻²² I have tried them in almost every pruritic eruption seen in my office, from industrial dermatitis to dermatitis herpetiformis. About 20 per cent of the patients acquired some temporary relief, even those with the latter disease. With the exception of urticaria the pruritus recurred despite the fact that the patient continued to take the medication, in chronic urticaria relief stopped with cessation of the drug.

On the other hand new untoward effects are being added to those already known. Drowsiness, dizziness, weakness and nausea are the reactions most frequently encountered. Sixty-three per cent of patients in one series experienced side reactions, the chief one being drowsiness of varying degrees up to narcolepsy.²³ After taking 300 mg. of Benadryl for three days, 1 patient complained of palpitation, dimmed vision, malaise without drowsiness and heartburn with nausea. After the next regularly scheduled dose (making a total of 350 mg.) the patient was found unconscious in bed, cold, pale and pulseless. On the eleventh hospital day Benadryl was again started under careful observation. Again after 300 mg. for three days the patient had similar symptoms.²⁴ Borman²⁵ reports a case in which the patient became lethargic, confused and disoriented from an overdose of Benadryl, reported to be 2000 mg. in forty-eight hours. Slater and Francis²⁷ recently discussed the use of Benadryl as a contributing cause of an accident.

Granulocytopenia has been reported from the use of Pyribenzamine.²⁶ In 2 cases I have seen cutaneous eruptions following its administration. One was a papular eruption that disappeared with discontinuance of the drug and recurred with a test dose. The second occurred in a man who presented an extensive purpura with thrombotic ulcerations on the legs following the prolonged use of Pyribenzamine.

Para-aminobenzoic acid in combination with proper supportive therapy has relieved Rocky Mountain spotted fever. The results in 5 patients with this disease suggest that deaths from this

malady may be practically eliminated by such combined therapy " "

The pigmentation of adrenocortical deficiency has been arrested by grafts of adrenal glands, adrenocortical extracts and the synthetic desoxycorticosterone acetate.

Cutaneous eruptions have so many etiologic factors that no one remedy can be specific. Urticarial eruptions may be seen with almost any systemic disturbances, hence the varied medication, such as vitamin K.²⁷

The use of vitamin A in skin diseases still commands attention. Much study has recently been devoted to the possible connection between certain cutaneous diseases and the levels of vitamin A in the blood plasma. Two British investigators²⁸ found little difference in the plasma vitamin A levels in 116 dermatologic patients and 116 control patients — a mean value of 116 international units of plasma in patients with skin disease and 113 international units in the controls. In 6 cases of Darier's disease, 2 of pityriasis rubra pilaris and 3 of ichthyosis, however, the mean level of vitamin A in the plasma was 77 international units. In the patients with Darier's disease and pityriasis rubra pilaris the administration of large doses of vitamin A concentrate resulted in an eventual plasma vitamin A level considerably above normal values. In 2 of the patients with Darier's disease the skin became normal or nearly so after treatment with vitamin A and Grenz rays. Two of the patients with pityriasis rubra pilaris showed some, but incomplete, improvement of the skin when the plasma vitamin A reached normal or higher than normal levels.²⁹

Encouraging results have been obtained in ichthyosis by Gordon,³⁰ who postulates two types of therapy, the combination of which have brought him great success. Therapy consists of daily baths in 3 per cent sodium chloride solution followed by 10 per cent sodium chloride in hydrous wool fat and vitamin A internally in daily doses up to 200,000 units, with bile salts and neostigmine. Complete cure was effected in 1 case fifty-one days after treatment was started.

Charpy,³¹ in France, and Dowling and Thomas,³² in England, have reported extremely encouraging results with calciferol in the treatment of lupus vulgaris. Vitamin D₃ in propylene glycol was administered by mouth to a series of 39 patients, some of whom had old, stubborn and extensive lesions. Charpy considers a high calcium intake a necessary adjunct to calciferol therapy in this disease. The quantity of sodium chloride ingested was reduced. All 39 patients treated were completely cured, 12 of them by internal therapy alone.

At the last meeting of the Society for Investigative Dermatology Curris et al.³³ reported the successful use of calciferol and dihydrotachysterol therapy, with and without added calcium, in the treatment of sarcoid.

Norman²⁷⁷ believes that vitamin D therapy, rather than parathyroidectomy, is the treatment of preference in scleroderma and the related disorders that are accompanied by hyperfunction of the parathyroid glands. He suggests that chronic overfunction of these glands constitutes a common denominator in scleroderma, dermatomyositis, chronic arthritis, Raynaud's disease and arteriosclerosis. He reports 3 cases of sclerosis, all with skin manifestations and apparently some muscle and tendon involvement. In all the cases improvement to the point of complete rehabilitation occurred, with restoration of normal skin and presumably a normal condition of the arterioles. Bernstein and Goldberger^{276, 279} report the relief of scleroderma by dihydrotachysterol (AT-10). This substance, which is formed when tachysterol — one of the irradiation products of ergosterol — is treated with sodium and propyl alcohol, has a mild effect on increased excretion. In these effects it falls between vitamin D and parathyroid hormone. Dihydrotachysterol causes a marked increase in urinary phosphorus excretion as compared with vitamin D.

I have used AT-10 in 5 cases — 3 localized and 2 generalized. The results were somewhat encouraging in the localized but disappointing in the generalized cases. I have, however, had the same results with other medication. Careful laboratory studies of patients must be made during therapy with large doses of vitamin D. Kaufman et al²⁸⁰ furnish fairly conclusive evidence that their patient died of high-potency vitamin D (ertron) intoxication.

Scleroderma is apparently associated with parathyroid dysfunction — either hyperfunction or hypofunction. Repeated serum calcium, total protein and phosphorus determinations should be done to determine the classification of the patient. If he falls in the hypoparathyroid group, dihydrotachysterol is the drug of choice. If he falls in the hyperparathyroid group, a partial parathyroidectomy should be performed, followed by large daily doses of vitamin D²⁸¹⁻²⁸³. Cytochrome C may help. This substance, a protein normally present in all living tissue, may be injected to combat tissue anoxia. Proger and Dekaneas²⁸⁴ believe that conditions in which anoxia is thought to play a role might be benefited by the injection of cytochrome C. Since there is considerable unused oxygen in venous blood, even in severe cases of anoxia, the role of cytochrome C is to promote utilization of the oxygen by tissues²⁸⁴.

Spies^{285, 286} reported prompt regeneration of the blood and profound improvement in the glossitis following the administration of synthetic folic acid to 2 patients with macrocytic anemia in relapse and pellagrous glossitis.

New vitamins are constantly appearing. In 1939 Scarborough²⁸⁷ presented evidence from experiments on human subjects to prove the existence of a factor decreasing capillary fragility, the factor being

vitamin P. Rutin, which like vitamin P is a flavone glucoside, is supposed to have the same properties. According to Griffith²⁸⁸ it is a constituent of a variety of plants, including tobacco, garden rue, forsythia, elder flowers and violets. He administered rutin to 11 patients, capillary fragility became normal in 8 of these cases within two months after the beginning of medication.

Rutin therapy has been used in hereditary hemorrhagic telangiectasia²⁸⁹. Kushlan²⁹⁰ gave a patient rutin in doses of 40 mg three times daily. A remarkable change in the character of the bleeding was noted twenty-four hours after the start of medication. The daily epistaxis and bleeding from the gums ceased for the first time since childhood and had not recurred at the time of writing.

A recent editorial seems somewhat timely. It reads as follows:

Rutin is a new agent for which certain therapeutic claims have been made with reference to disturbances of capillary fragility and permeability. Rutin is said to be a glucoside of quercetin, which can be obtained from various leafy plants and flowers. Just how it is supposed to act is not clear. When we recall that capillary permeability and so-called "fragility" may be altered either by disorders of the capillary membrane itself or on the other hand by changes in the cement substance between the endothelial cells, and when we realize that the cement substance in turn is affected by all sorts of variations in reaction and in concentration of various blood ions, it becomes clear how complicated the situation is and how difficult a really critical evaluation of any substance from the standpoint of its effect on "capillary fragility" must be. To call rutin vitamin "P" or give it such a general designation as the capillary permeability regulating vitamin hardly seems justifiable as yet. It has been found, however, that the use of rutin may be followed by lessening of capillary permeability under certain conditions as measured by a standard petechiometer test. Since the material seems to produce no toxic effects in man and furnished in the form of a small, practically tasteless pellet which can be taken simply by mouth, a thorough appraisal in clinical conditions in which capillary fragility is altered seems worth while.²⁹¹

Perhaps rutin is not harmless. Two cases of subconjunctival hemorrhages are reported — the first after approximately four and eight weeks of rutin therapy, and the second after one day's administration of this drug²⁹².

The scope of penicillin is constantly enlarging. It has been used in the treatment of patients with various cutaneous infections²⁹³⁻²⁹⁶. Zee²⁹⁷ reports a case of relapsing febrile nonsuppurative panniculitis (Weber-Christian disease) observed in a twenty-three-year-old soldier, the lesions being proved by biopsy. Treatment with sulfadiazine was unsuccessful. The findings and symptoms were progressive until the institution of treatment with penicillin. Doses of 20,000 units each were given intramuscularly for a period of fifteen days, to a total of 2,360,000 units. Within three days after the institution of treatment the temperature returned to normal and remained there. No further lesions were noted. The nodules regressed, and during a period of three and a half months there was no recurrence of symptoms or findings.

Physicians treating arthritis with gold are now observing the reactions described years ago by dermatologists who first used this metal in the treatment of discoid lupus erythematosus. For combating these reactions they are fortunate to be able to obtain BAL. This substance, whose chemical name is 2,3-dimercaptopropanol, was developed by the British as an antidote to arsenical blister gases.¹⁹⁹ But long before World War II — indeed during the era of Paul Ehrlich — studies leading to the recognition of the clinical value of BAL were being made.²⁰⁰ Two serious reactions to gold salt — thrombopenic purpura and granulocytopenia — are described in an article by Lockie et al.²⁰¹ Spectacular recovery occurred in each case. The usual course of such complications appears to have been definitely altered by BAL therapy. No change in the status of the arthritis occurred. Ragan and Boots²⁰² used this drug successfully in 5 patients with dermatitis due to gold. Successful treatment with intramuscular injections of BAL was also reported by Cohen and his associates²⁰³ in 5 cases of acute poisoning due to gold and 1 of acute poisoning due to arsenic. Transient symptoms of BAL toxicity included a sense of warmth in the mouth, salivation, flushing of the face, conjunctival injection, lacrimation and pains in the arms and legs. The number of cases reported is too small to justify a definitely favorable interpretation of results, and yet the prompt clinical effects are impressive and warrant more extended use of this drug in the relief of gold intoxication, so that eventually chrysotherapy of rheumatoid arthritis may be employed more generally and with less fear of the devastating toxic reactions.²⁰⁴

Hartman²⁰⁵ acclaims the use of hormones in dermatology, citing the diseases due to their deficiency or absence of a specific endocrine product responding to substitutive therapy, disorders not due to a specific hormone deficiency, but in which a hormone has a specifically useful effect, and those in which endocrine malfunction may be a precipitating or aggravating factor.

In the first group he mentions adrenocortical extracts and synthetic desoxycorticosterone acetate in Addison's disease, desiccated thyroid or thyroxine in myxedema, pituitary or chorionic gonadotropin in urticaria and dermatographia, estrogens in pruritus vulvae and senile vaginitis, and the value of insulin in xanthoma diabetorum and other skin manifestations of diabetes mellitus.

The second group includes epinephrine, pitressin and insulin in urticaria and angioneurotic edema, parathyroid in papular urticaria, pitressin in herpes zoster and desiccated thyroid in xanthoma tuberosum, xeroderma, ichthyosis and seborrheic dermatitis. Estrogens are suggested for therapy in Cushing's syndrome, gonorrheal vulvovaginitis before puberty and vulvovaginitis due to *Trichomonas* during and after the menopause.

In the third classification there is an interesting discussion of the relation of thyroid or gonadal malfunction in atopic dermatitis, urticaria and acne vulgaris. Hartman²⁰⁶ states that in the present state of knowledge no good can be done to the acne or atopic dermatitis in male patients and that conceivable harm can be done to the pituitary-gonadal equipment. In the female one gets the impression there are menstrual and premenstrual types, but the persistence of the lesions makes distinction difficult.

I might suggest a word of caution to gynecologists and dermatologists. Three indignant women have sought my advice regarding the increased growth of hair on the face subsequent to the injection of testosterone.

CONCLUSIONS

After reading the foregoing discussion, the physician should realize that any cutaneous disturbance that resists simple medication warrants thorough study of the patient. Even a simple wheal may be the beginning of a serious illness, likewise, the sudden onset of a cutaneous eruption in an extremely sick patient may prognosticate a fatal ending. Having remarked on the necessity for the increased use of powers of observation and palpation among physicians, I might decry the extreme to which these powers are used by some dermatologists, who frequently rely too much on observation of cutaneous lesions and neglect complete physical examination and necessary laboratory procedures.

assumption of previous hypertension, and in this terminal period the blood pressure was low.

Could the patient have had multiple pulmonary infarcts resulting in cardiac failure of the cor-pulmonale type? There is no note of an accentuation of the pulmonary second sound. It is true that the systolic murmur may have been pulmonary in origin, but we should have more evidence of right-sided heart strain as the primary difficulty. There were no acute episodes in the past suggesting pulmonary infarction. As for the unexplained primary myocardial lesion, the unusual types of true myocarditis that we have seen in these sessions, such as those related to the sulfonamides or isolated or diffuse myocarditis, such cases are usually seen in younger patients, certainly, in the type associated with virus infection, there is very often a story of pre-existing respiratory infection. There is no reason to believe that there was an aortic aneurysm, whether on an atherosclerotic or on a syphilitic basis. We have, however, no x-ray studies on this patient.

To return to the evidence as it is given to us we should think of calcific aortic stenosis. The points that go with that diagnosis are the male sex, the fact that cardiac failure often appears late in life, the large left ventricle, congestive failure with normal rhythm and the rather rapid downhill course. I am disturbed particularly by the electrocardiographic findings in that there was no left-axis deviation, which one would expect in prolonged disease of the aortic valve. However, yesterday in the clinic we saw a man who had had a known aortic lesion of rheumatic origin for thirty years in which there was little if any left-axis deviation. To get around that difficulty one might mention the possibility of a complicating mitral lesion with a balanced electrical effect on the electrocardiogram, of which we have no clinical evidence, or we might introduce the Bernheim syndrome, which is a bulge of the septum into the right ventricle in lesions that produce marked enlargement of the left ventricle. However, one would expect such a condition to interfere with filling of the right ventricle, and that has been brought forth as an explanation for the signs of primary right-sided heart failure in systemic hypertension.

I know that we have frequently been found wanting in our ability to diagnose calcific aortic stenosis in elderly patients who are in extremis, or who are admitted to the hospital for surgical operation, and who never knew they had anything wrong with the heart. One can infer that a businessman may have had physical examinations throughout his lifetime or even tried to take out life insurance and may have known something about heart disease in the past, but the record contains no such statement. The fact that he was given nitrates previously suggests that before admission he had a doctor, who might tell us about the physical findings. But I confess that I shall have to say that this diagnosis

of aortic stenosis appeals to me most. There may have been in the background a congenital bicuspid aortic valve, or some stigmas of a previous rheumatic infection. The final episode, which was associated with pulmonary edema and deep cyanosis, suggests a terminal pulmonary infarction. Statistically I should judge that that would be found. On the other hand patients with aortic stenosis, with characteristic encroachment on the coronary ostia, may die suddenly, and in this case the cyanosis could well have been due to the extreme degree of moisture in the lungs without pulmonary infarction.

Dr TRACY B. MALLORY: Dr Chapman, would you like to comment?

Dr EARLE M. CHAPMAN: I arrived too late to hear all the discussion but at this point I want to congratulate Dr Sprague on his astute diagnosis. I am the physician who saw the patient and followed him for some three years. He came to me primarily as a patient with mild diabetes and merely for control of the diabetes. His health had been otherwise good, he had no primary complaint and claimed that he was well, and I thought him to be so. Examination disclosed the harsh systolic murmur, loudest along the left border of the sternum and apex. I thought that it was somewhat transmitted in the aortic area, and yet I did not interpret it at the time as a murmur of aortic stenosis. I thought, rather, that perhaps in youth he had had rheumatic infection and might have mitral insufficiency to a mild degree. He developed a papilloma or carcinoma of the bladder in the summer of 1946, which was treated by fulguration. He withstood the procedure very well, came home and resumed his usual activity. At all times the rhythm was regular, and the rate slow. There was no indication of heart failure until the spring of 1947, when he began to complain of some shortness of breath. He knew that he was aging, — he was by that time sixty-eight years old — and in climbing the subway stairs was short of breath when he reached the top. At other times he had a feeling of pressure under the sternum — not pain, but simply pressure. This was interpreted by me as being mild angina, and I gave him 0.1 gm. of Aminophylline three times a day. He was not given nitroglycerin. In August, while attempting to transport his wife, who is an invalid, in a sedan chair, with the aid of another friend, he suddenly had a violent attack of shortness of breath. About two weeks later I visited him at his home. At that time he was in the garden, and we had to walk across the entire garden and up to the bowling green and then up another 20 feet to the house and up two flights of stairs. I observed no undue dyspnea or complaint on his part, although I was definitely short of breath. At that time he did not seem to have any signs of congestive failure, and I saw no reason to give digitalis. But I arranged for a consultation with a

member of the Cardiac Department That was on September 8 You have heard the rest of the history He died on September 20 I did not see him in the last illness, which terminated in the course of twenty-four hours

A PHYSICIAN Did he have an aortic thrill?

DR CHAPMAN No, there was no thrill

DR SPRAGUE Some years ago, when we collected a series of cases of "pure" mitral regurgitation and "pure" mitral stenosis, in the group of twenty patients with "pure" mitral regurgitation the systolic murmur was loudest at the apex² We followed these 20 cases for several years, and 2 of the 20 patients with what we thought was originally mitral regurgitation turned out later to have aortic stenosis and the murmur became more intense at the aortic area

CLINICAL DIAGNOSES

Acute pulmonary edema
Coronary thrombosis with myocardial infarction?
Coronary heart disease
Angina pectoris

DR SPRAGUE'S DIAGNOSIS

Calcific aortic stenosis

ANATOMICAL DIAGNOSES

Calcific aortic stenosis
Acute pulmonary edema, severe
Arteriosclerosis

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed a considerably hypertrophied heart, which weighed 595 gm, with calcareous aortic stenosis and no other valvular lesions The cusps of the aortic valve were not interadherent but were markedly calcified, and it was impossible to thrust even the tip of the finger between the calcified masses The coronary arteries were sclerotic and calcified in part but showed no areas of significant narrowing and no evidence of old thrombosis The myocardium was free from scars grossly and microscopically, so that all our evidence is that of a pure aortic stenosis The lungs of course were extremely heavy, weighing over 2400 gm — as marked a pulmonary edema as one ever sees There were no other significant findings and no evidence of recurrence of the tumor The degree of passive congestion in the liver, spleen and kidneys was very slight

DR SPRAGUE Was there pulmonary infarction?

DR MALLORY No

DR SPRAGUE Had he had x-ray studies prior to the ones of the heart? Was he a thick individual or thin?

DR CHAPMAN He was a thin man He had an increased anteroposterior diameter of the chest, a barrel-shaped chest, although he had small arms and legs

DR SPRAGUE The most useful thing in diagnosis of this sort, of course, is careful fluoroscopic examination If the examiner takes a long enough time to get his eyes accommodated he can usually see calcifications in the aortic valves in an elderly person with aortic stenosis and observe the characteristic rotary motion of the valve

DR CHAPMAN He had fluoroscopic studies, and that was not observed

CASE 33512

PRESENTATION OF CASE

A fifty-eight-year-old shoe-store operator entered the hospital because of a lump in the neck

The mass suddenly appeared nine weeks before entry while the patient was taking a bath It was in the anterior portion of the neck occupying most of the space between the chin and sternum, and was painless, although for several days it was tender, with redness of the overlying skin The mass had diminished slightly in size There had been no other symptoms, and the patient felt quite well Two determinations of the basal metabolic rate taken soon after the lump appeared were reported as normal

The patient had had diabetes for three years and took 18 units and 36 units of regular insulin on alternating days The urine remained sugar-free most of the time He had been treated for syphilis twenty-eight years before entry, and several blood tests since then had been negative

Physical examination revealed a firm, rubbery, rounded mass, measuring 8 by 7 by 4 cm, projecting from the thyroid area, rather more so on the right It was slightly warm and nontender, and no bruit or pulsation was present The mass was fixed but moved vertically with swallowing Two small, firm lymph nodes were present at the lower end of the left side of the mass at the base of the sternocleidomastoid muscle A harsh Grade II systolic murmur was audible at the apex and base of the heart There were small bilateral inguinal hernias

The temperature was 97.8°F, and the pulse 80 The blood pressure was 180 systolic, 108 diastolic

Examination of the blood disclosed a red-cell count of 4,980,000, with a hemoglobin of 13.5 gm, and a white-cell count of 7700, with 66 per cent neutrophils The urine had a specific gravity of 1.022 and gave a ++ test for albumin and an orange test for sugar The sediment contained an occasional red cell and pus cell The fasting blood sugar was 173 mg, and the nonprotein nitrogen 31 mg per 100 cc The stools were guaiac negative

X-ray examination showed a mass in the upper anterior portion of the mediastinum measuring 8 cm across and extending down beneath the manubrium sterni. The esophagus was deviated slightly to the left but was not compressed. In the right lower-lung field was an area of increased density superimposed over the ninth rib posteriorly and the fifth rib anteriorly. This was not seen in a lateral view.

The patient was given no specific therapy. On the fourth hospital day 500 microcuries of radioactive iodine was given, and surface counts showed less activity over the tumor. On the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR EDWARD HAMLIN, JR. The first intriguing remark in the protocol is that the mass suddenly appeared while the patient was taking a bath. If we accept that as a valid observation, we would immediately come to a full stop, for there is no condition of which I am aware in which a mass of this size can suddenly appear while a patient is taking a bath. Therefore, we must assume that the patient first noticed it then, but that it had been gradually appearing over an indefinite period.

For the moment I shall dispense with the diabetes and assume that it had no relation to the disease.

From the physical examination, one can only conclude that this mass was in some way related to the thyroid gland, since it moved on swallowing. Assuming that this is so, there are three entities that must be considered in the differential diagnosis: cancer, inflammation and a cyst or involutional type of goiter. The fact that the mass was fixed makes it appear unlikely that a simple colloid or involutional goiter was responsible. It is frequently impossible to differentiate chronic thyroiditis and cancer of the thyroid gland. The two small firm lymph nodes, which were found at the lower end of the left side of the mass at the base of the sternocleidomastoid muscle, could be attributed to either disease. The mass seen in the right lower-lung field, only in the anteroposterior view, if we think in terms of one diagnosis could be associated only with cancer.

Nothing else in the protocol seems to be at all helpful in the differentiation of these two conditions. It would be nice to have had a report on whether the vocal cords moved equally.

DR BENJAMIN CASTLEMAN. I note in the record that the larynx was examined by a member of the Eye and Ear Infirmary and that the vocal cords were found to be normal.

DR HAMLIN. Cancer of the thyroid gland frequently invades the region of the recurrent laryngeal nerve or nerves and produces a paralysis, which is almost unheard of in any other condition of the thyroid gland.

Probably the only sure way to make an accurate diagnosis was the method employed, which was operation with a biopsy—a frozen section of the tissue itself—and only then could the proper treatment be carried out.

One obscure sentence in the protocol is that radioactive iodine was given and surface counts showed less activity over the tumor. Less activity than what? In either thyroiditis or carcinoma the amount of iodine that would be absorbed might be very low indeed, and the activity would certainly be less than that over a normal thyroid gland.

On the whole, with a questionable lesion of the lung, I should be inclined to call this carcinoma of the thyroid. Certainly, in several cases that we have recently seen, such a carcinoma was an extremely rapidly growing and very malignant tumor, which I suspect that this proved to be. Therefore, carcinoma of the thyroid gland is my first choice, and the second is chronic thyroiditis.

DR WILLIAM M. JEFFERIES. When this patient was seen at the Thyroid Clinic there was considerable speculation concerning the diagnosis of the mass in the neck. On palpation this was thought to feel more like carcinoma, but the history of sudden appearance could not be shaken. The patient maintained that the mass had not been present prior to the day he first noticed it since he previously had not seen or felt any unusual swelling in the course of daily shaves, nor had he experienced difficulty in buttoning his collar. His wife corroborated this statement. The associated signs of inflammation, notably tenderness, heat and redness, were also unusual for carcinoma of the thyroid gland, although it could conceivably have resulted from sudden hemorrhage into a rapidly growing tumor.

For these reasons other possibilities were considered. Sudden hemorrhage into a cyst of the thyroid gland might account for the acute enlargement with associated inflammatory signs, but the neighboring lymphadenopathy would be unexplained. Acute thyroiditis might produce such a picture, but with a swelling of this size one would expect to find associated constitutional signs such as fever and leukocytosis. With the history of syphilis in the past, gumma of the thyroid gland was mentioned, but this is such an extremely rare condition (and the patient had apparently had adequate treatment) that it was thought to be unlikely. It was therefore believed by the majority of examiners that this was most probably a malignant tumor.

The studies with the Geiger counter after the administration of a tracer dose of radioactive iodine revealed less radioactivity over the main portion of the mass than over its posterolateral edges, suggesting that the functioning thyroid tissue had been displaced posteriorly by the mass.

CLINICAL DIAGNOSIS

Carcinoma of thyroid gland?

DR. HAMLIN'S DIAGNOSIS

Carcinoma of thyroid gland

ANATOMICAL DIAGNOSIS

Carcinoma of thyroid gland, giant-cell type

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN At operation a firm somewhat fluctuant mass adherent to the strap muscles was disclosed. Aspiration produced a cloudy sero-sanguineous material containing small fragments of tissue, which on frozen section seemed to be necrotic, with a predominance of polymorphonuclear cells. A biopsy of the thick wall of the mass revealed a very undifferentiated carcinoma, and a total thyroidectomy was performed.

We received about 120 gm of tissue containing nodules of necrotic tumor, some normal thyroid tissue and several lymph nodes that proved to be uninvolved, but the tumor had invaded some of the adjacent strap muscles. The semifluctuant area originally observed and aspirated was a focus of necrosis and hemorrhage and probably accounted, in part at least, for the sudden appearance of the mass.

Microscopically this tumor fits into the more malignant group of thyroid tumors, in which the cells are very large and undifferentiated, some being spindle-shaped and others multinucleated tumor giant cells. Because one portion is sometimes composed predominantly of spindle-shaped cells, the tumor has often been called a sarcoma or carcinosarcoma. However, most pathologists now believe that this type of tumor is fundamentally epithelial and prefer the term "giant-cell carcinoma."

Postoperatively the patient received a total of 5700r to the anterior portion of the neck and mediastinum over a period of one month.

THE WISE MEN

Among the many inspiring stories associated with Christmas is the familiar one of the wise men who came from the east to Bethlehem. They were only three in number, they were guided through the darkness of the desert by the light of a star, and when they had found that which they sought they left gifts and departed into their own country by another way, fearing Herod.

The proportion of wise men to foolish in the world today is generally the same as it was when Christianity dawned, and we still have our Herods. Men and women continue to be of about the same material that their inheritance has determined, polished or marred by that with which it comes in contact. They are still ignorant, passionate, selfish, unsophisticated, cruel and kind grasping and

They have, however, something that the world once lacked — the same star to guide them that the wise men followed.

No one who has been exposed to the great religious forces of the world can escape being influenced in some positive way by them. Names and forms matter little. Each has its divine leadership, each has its Herods, each its crosses, its stars or its crescents, each has its wise men and each its growing tolerance.

It is on this that the salvation of the future will depend. It is on the mutual respect and forbearance and understanding that must be building between races and colors and creeds each for the others.

SHORTENED ISOLATION REQUIREMENTS

THE advance of knowledge regarding the common communicable diseases has resulted in the shortening of many isolation requirements. A case of meningococcal meningitis, under prompt and adequate sulfonamide treatment, can be considered no longer infectious after five days, and the same thing may be said of the quarantine of treated contacts. Recent clinical investigations have shown that the virus of chicken pox is apparently spread from the respiratory tract for two to four days prior to the eruption, and that the period of infectivity does not appear to extend beyond the fifth day after the appearance of the skin lesions.¹ According to these observations, prolonging the isolation beyond one week, until the scabs fall off, seems to be unnecessary. On the other hand, the old idea that smallpox is contagious for the duration of the crusts is borne out by recent observations.² The virus of mumps has never been isolated from the saliva beyond seventy-two hours of the onset of the parotitis, yet no experimental evidence is at hand to determine whether other late manifestations of this disease imply a renewed secretion of the virus through the salivary glands. Therefore, precautions should be continued until this point has been determined.

The infectivity of measles begins during the prodromal catarrhal stage and extends through the height of the eruption, falling off promptly as the rash fades. Again, in whooping cough, it has been found that 71 per cent of cases originate from ex-

posure to patients in the prodromal catarrhal stage, 18 per cent from exposure in the first week of the paroxysmal stage, 8 per cent in the second week, and 2 per cent in the third week.³ This curve conforms fairly closely to that of positive cultures obtained with cough plates.⁴ In this disease, however, the duration of infectivity, although diminishing materially, warrants isolation for a period of at least three weeks, and even longer for the protection of infants in the first months of life. The problem of isolation for rubella is especially concerned with the protection of women in the early months of pregnancy. Here, as in these other diseases, it is to be emphasized that the period of infectivity begins prior to the stage in which the disease can be recognized by the classic symptoms and that isolation is usually applied too late to be more than partially effective.

Poliomyelitis and scarlet fever present extraordinary problems of isolation because both diseases are peculiar manifestations of widely disseminated infections that, in minor forms, go unrecognized except by cultural methods. New or renewed concepts arrived at through laboratory experiments are often in conflict with observations based on careful field studies in epidemiology, which point to their predominantly air-borne and person-to-person dissemination. Nevertheless, a shortening of the isolation requirements of both these diseases is in progress owing to the results of these studies.

State boards of health are usually better informed in such matters than local boards of health. The former establish minimum requirements of isolation and quarantine, whereas the latter are free to impose stricter measures. If a local board desires to try out a time limit below the minimum established by state or federal standards the right to do so should be granted. Indeed, permission to do so should be granted to qualified medical directors of educational institutions by local and state authorities. In support of this contention one can point to the classic method of curtailing scarlet fever isolation in the city of Bergen, Norway, twenty-five years ago,⁵ recently adopted with modification in parts of the United States, and to the satisfactory results of shortened isolation procedures in other common communicable diseases at Rugby School in England.⁶

The health authorities of New England have always been ready to co-operate in any well planned studies related to the economic factors of disease control.

DEATHS

COYNE — Thomas J. Coyne, M.D., of Roxbury, died on December 4. He was in his seventy-fifth year.

Dr. Coyne received his degree from Tufts College Medical School in 1901. He was a member of the staffs of St. Elizabeth's, St. Margaret's and Harley hospitals. He was a fellow of the American Medical Association.

Two sisters and a brother survive.

MENARD — Leon J. Menard, M.D., of Fall River, died on August 9. He was in his fifty-sixth year.

Dr. Menard received his degree from University of Vermont College of Medicine in 1919. He was formerly a member of the Fall River Board of Health and was a member of the staff of St. Anne's Hospital.

His widow, three sons, two brothers, three sisters and one grandchild survive.

STONE — Jane Gray Stone, M.D., of Boston, died on May 6. She was in her seventy-fourth year.

Dr. Stone received her degree from Tufts College Medical School in 1911. She was a former member of the Massachusetts Medical Society.

Three brothers and a sister survive.

MISCELLANY

NOTES

The following appointments to the teaching staff of Harvard Medical School were recently announced: Marvin Alorton Nachlas, of Boston (A.B. Johns Hopkins University 1940, M.D. Johns Hopkins University 1943), assistant in anatomy; George William Lynch, of Boston (A.B. Harvard University 1929, M.D. Harvard University 1933), assistant in medicine; Peter Bernard Golden, of Boston (S.B. University of Wisconsin 1938, M.D. University of Wisconsin 1940), assistant in surgery; Thomas Simpson Risley, of Waterville, Maine (S.B. Harvard University 1937, M.D. Harvard University 1941), assistant in surgery; Stanton Lee Eversole, Jr., of Charlottesville, Virginia (M.D. University of Virginia 1944), teaching fellow in physiology; Sidney Cobb, of Fort Devens (S.B. Harvard University 1938, M.D. Harvard University 1942), research fellow in biologic chemistry; Harold Mankin, of Teaneck, New Jersey (A.B. Columbia University 1938, M.D. Harvard University 1942), research fellow in biologic chemistry; Robert Buka, Jr., of New York City (A.B. Harvard University 1938, M.D. University of Pittsburgh Medical School 1942), research fellow in medicine; Pedro Maximino Catoggio, of Republica Argentina (M.D. Universidad Nacional de La Plata 1943), research fellow in medicine; Harvey Shields Collins, of Boston (S.B. University of California 1935, A.M. Harvard University 1940, M.D. Harvard University 1943), research fellow in medicine; David Thomas Dresdale, of

Brooklyn New York (M.D. College of Physicians and Surgeons Columbia University 1942) research fellow in medicine Paul Fremont-Smith of Cambridge (M.D. Harvard University 1946), research fellow in medicine Edward Phillips of Los Angeles, California (M.D. University of Southern California 1942), research fellow in medicine David Harris Solomon, of Brookline (A.B. Brown University 1944 M.D. Harvard University 1946) research fellow in medicine Edward Donnell Thomas of Boston (A.B. University of Texas 1941 A.M. University of Texas 1943 M.D. Harvard University 1946) research fellow in medicine Nilo Oskar Burger Hallman of Helsinki Finland (M.D. Medical School of University of Helsinki, Finland 1943) research fellow in pediatrics, Daniel Charles Tosteson, of Wauwatosa Wisconsin (no degree) research fellow in physiology, Eugene Leonard Watkins of Worcester (A.B. Clark University 1940 M.D. Harvard University 1943) research fellow in surgery Lawrence Chappell Kingsland Jr. of Wakefield (S.B. Mass Institute of Technology, M.D. Harvard University 1940) instructor in pediatrics John Schulman, Jr., of New York City (S.B. Yale University 1942 M.D. University of Pennsylvania 1946), research fellow in medicine William A. Messner, of Newton Center (A.B. University of Oregon 1935 M.D. University of Oregon Medical School 1938) instructor in pathology, William Fielda Cavness of Raleigh North Carolina (A.B. University of North Carolina 1929, M.D. McGill University Medical School 1943) assistant in psychiatry, Janice Hodges, of Metairie, Louisiana (S.B. Louisiana State University 1942, M.D. Louisiana State University Medical School 1944), assistant in psychiatry David John Myerson, of Brookline (A.B. Harvard University 1940, M.D. Tufts College Medical School 1943) assistant in psychiatry, Jackson Smith, of Normal, Oklahoma (A.B. University of Oklahoma 1939 M.D. University of Oklahoma 1943) assistant in psychiatry, Fadil Adiyadi, of Mosul Iraq (M.D. Faculty of Medicine of Paris 1937), research fellow in bacteriology and immunology, Nusret Hassan Fisek, of Ankara, Turkey (M.D. Medical School of University of Istanbul 1938), research fellow in bacteriology and immunology, Ching teng Teng, of Chungking Szechuan Province China (S.B. Yenching University 1935, M.D. Peiping Union Medical College 1941), research fellow in biologic chemistry Norman Robert Stanley Hollier, of Ottawa, Ontario (B.Sc. University of Alberta 1944 Ph.D. McGill University 1947) research fellow in physical chemistry Rudolf Georg Straessle of Berne Switzerland (Ph.D. University of Berne 1946), research fellow in physical chemistry Robert Peter Brittain, of Scotland (B.Sc. 1939 B.L. 1941 M.A. 1943, M.B., Ch.B. 1943, LL.B. 1944; D.P.A. 1943—Glasgow University), research fellow in legal medicine Arnold Michael Cooper, of Roselle New Jersey (A.B. Columbia College 1943, M.D. University of Utah Medical School 1947) research fellow in medicine Lilian Recant, of New York City (A.B. Hunter College 1941 M.D. Columbia University 1946), research fellow in medicine, and Robert Warren Reifenshtein, of Syracuse, New York (A.B. Syracuse University 1943 M.D. Syracuse University 1945), research fellow in medicine.

ROCHE-ORGANON AWARDS IN ENDOCRINOLOGY

Three awards of \$500 each have been sponsored by Roche-Organon Inc. hormone manufacturers, for scientists in recognition of their recent, outstanding research in the following fields of endocrinology: animal experimentation hormone chemistry and clinical endocrinology. The winners of the 1947 awards are Dr. Fuller Albright (clinical endocrinology) Dr. Robert D. H. Heard (hormone chemistry) and Dr. Dwight J. Ingles (animal experimentation). The winners of the awards were selected by the Committee on Awards of the Laurentian Hormone Conference which consists of Dr. Roy G. Hoskins chairman and Drs. Edwin B. Astwood Thomas F. Gallagher Allan T. Kenyon Robert L. Noble and Abraham White. The awards were presented at the 1947 Laurentian Hormone Conference held recently at Sainte Adèle, Quebec, Canada.

MASSACHUSETTS CENTRAL HEALTH COUNCIL

Appointment of a nutrition committee, consisting of the following members, was recently announced by the Massachusetts Central Health Council: Frederick J. Stare, M.D.

(chairman) professor of nutrition and head Department of Nutrition Harvard Medical School associate in medicine, Peter Bent Brigham Hospital member Food and Nutrition Board National Research Council and formerly consultant in nutrition to the Surgeon General United States Army, Charles C. Lund M.D. assistant professor of surgery Harvard Medical School, and visiting surgeon Boston City Hospital George Thora M.D. professor of medicine Harvard Medical School and physician-in-chief Peter Bent Brigham Hospital Charles S. Davidson M.D. instructor in medicine Harvard Medical School assistant physician, Thorndike Memorial Laboratory, and assistant director, Fourth Medical Service Boston City Hospital, and formerly consultant in nutrition to the Surgeon General, United States Army Robert Harris, Ph.D. professor of nutritional biochemistry Massachusetts Institute of Technology and consultant in nutrition to the Pan American Society and to the Quartermaster General United States Army, Elda Robb Ph.D. professor of home economics and head department of Home Economics Simmons College Mrs. Beulah Becker Marble formerly president American Dietetic Association Mrs. Emma May acting head Nutrition Board Massachusetts State Department of Health Miss May Foley extension nutritionist, Massachusetts State College, Amherst and Miss Jean Ackerman supervisor of nutrition Boston Visiting Nurse Association.

WORLD HEALTH ORGANIZATION

The World Health Organization of the United Nations demonstrated its effectiveness in the epidemic of cholera in Egypt this fall. An important part of the demonstration was the co-operation of various nations against a common danger.

More than 32 tons of vaccine, plasma and other supplies were shipped from New York by air. China made available 2,000,000 cc. of vaccine and Indo-China, Japan and Southern Korea more than 3,200,000 cc.

This is the first time in history according to the report released on December 1 that an epidemic spreading at a rate of more than a thousand new cases a day has been checked within six weeks of its onset. Final figures indicate that 20,129 cases occurred with 9,760 deaths. The case fatality rate was about 48.5 per cent, as compared with former rates in the vicinity of 85 per cent.

FELLOWSHIPS FOR RESEARCH IN OPHTHALMOLOGY

Dr. Thomas Duane of Harvard Medical School, and Dr. David Freeman of Yale University School of Medicine have been awarded fellowships for research in ophthalmology by the Eye Bank for Sight Restoration Inc. Dr. Duane will investigate the metabolism of the cornea under various conditions of storage to determine the factors that affect corneal tissue and make it unsuitable for corneal transplant, and Dr. Freeman will conduct an experiment in tissue transplantation to determine whether embryonic tissues can be grafted upon members of the same or different species. It is hoped that the knowledge acquired through these investigations will aid in the conservation of vision and the restoration of sight among thousands of persons.

CORRESPONDENCE

DIAGNOSIS FIRST

To the Editor: Many years ago Dupuytren told his students "Diagnosis holds the first rank in our science and is the most difficult part of it without an exact and precise diagnosis theory is always faulty and practice often incorrect."

After reading the article "Clinical Significance of Malignant Neoplasms of the Thyroid Gland" by Rogers et al. in the October 16 issue of the *Journal* I am convinced more than ever of the wisdom and soundness of Dupuytren's teaching.

If it is the chief duty of an attending physician to make a precise diagnosis and when a patient

is attended who has a nodule in the thyroid gland, I know of no way of making such a diagnosis without excising the diseased area and submitting it to a microscopist competent in the diagnosis of tissues

MALCOLM THOMPSON, M D

1711 Heyburn Building
Louisville, Kentucky

Dr Thompson's letter was referred to Dr Walter F Rogers, Jr, whose reply is as follows

To the Editor It would be difficult and unwise to question the wisdom of Dupuytren's maxim, which was quoted in Dr Thompson's letter, and it was not the purpose of our paper to create the impression that an exact and precise diagnosis is not desirable. On the other hand, the purpose was to discuss the incidence, course and importance of malignant neoplasms of the thyroid gland. This included such facets of the problem as the significant number of complications associated with operations on nontoxic goiters and recurrence or development of malignant lesions despite "prophylactic surgery."

Dr Thompson's letter indicates his belief that if a patient has a nodule in the thyroid gland it should be removed. We also concluded that most solitary nodules should be extirpated and examined microscopically by a pathologist, thus, it seems that here we are in essential agreement. It may be added that the diagnosis of a malignant neoplasm of the thyroid gland, even by histologic examination, is not always unequivocal or easy, for many pathologists admit the great difficulty of determining whether some thyroid nodules are or are not the site of malignant growth.

After data have been accumulated, it is not surprising that their interpretation may differ. However, when all aspects of the problem of malignant neoplasms of the thyroid gland are considered, our judgment of the evidence leads us to believe that it is wise to remove single nodules, but that the routine surgical extirpation of all nodular goiters is not necessary or advisable.

CONTRACEPTIVE CARE A REBUTTAL

To the Editor Is it a blot on the legislative escutcheon of Massachusetts to have overridden the previously proposed Sangerism? Are we wet blankets or wallflowers in a materialistic and pseudoscientific era to oppose such an enactment? I say pseudoscientific advisedly, any means which seems to justify an academic whim seems to be correct protocol. Is this the scientific method?

This pending bill is a further attempt to legalize the practice of birth control and as such has no place on our legislative referenda. Notwithstanding the pre-eminent roll call of co-sponsors it is my desire to discuss the amendment. The idea of giving contraceptive advice to married women is hardly commensurate with the practice of ethical medicine.

Ethics is nothing more or less than the science of morality. Morality is the norm which delineates between right and wrong. These norms were not established by us nor can they be transcended by us. This situation obtains in every field of endeavor, and by the same token it must be incumbent on every physician so to govern himself.

Is the giving of contraceptive advice right? Does it adhere to the moral law or is it a relative issue? I say, "No," because it is irrevocably alien to the primary ends of marriage. It is an unnatural and artificial frustration of a faculty given to us in marriage.

I am keenly aware of the many conditions precluding childbirth. Do these necessitate the use of means which are essentially wrong? Is not self-control the answer or does it imply courage and devotion? Is it too much to demand that men and women co-operate in a mutual effort to preserve their own integrity or does self-gratification take precedence over self-esteem? Self-control or intellectual discipline is not a trait peculiar to any religion but a rule taught and adhered to by those persons past and present who are the leaders in their fields or chosen profession.

Once the bill is passed, and herein lies the unseen danger, the remaining barriers of normalcy will have been lifted and promiscuity will be the keynote of a modern society. Advice

will be sought not only by those in ill health but by all and sundry who seek to follow the lines of least resistance. As it is unnatural to deprive a person of the right to conceive, so it is in contradistinction to the laws of nature to dispense advice frustrating its most sacrosanct privilege.

BED REST IN TREATMENT OF TUBERCULOSIS

To the Editor The Shattuck Lecture by Dr William Dock, which appeared in the May 22 issue of the *Journal*, is a valuable presentation and has widespread implications. The following comments apply only to the sections dealing with the circulation through the lungs. This article and others by Dr Dock on the same subject are indeed thought-provoking—I am referring to his studies on the blood supply to the lung apex in the upright and recumbent positions and the consequent effect on the incidence of apical tuberculosis and healing of this and other pathologic processes involving the apex of the lung.

Bed rest, as ordered by many physicians, and recumbent bed rest may be widely different. I have been in tuberculosis sanatoriums where most patients during the day are semi-recumbent, semiupright or upright in bed except for the total afternoon rest period of two hours. Dr Dock's reasons for flat bed rest differ from those commonly taught and printed. Cecil (*Textbook of Medicine* Sixth edition 1566 pp Philadelphia W B Saunders Company, 1943 P 290) implies that lessened respiratory activity is the important feature of bed rest and does not mention circulation. He also holds that lessened toxicity follows by reason of a decreased blood supply to the lung apex. Dr Dock reaches the same conclusion (lessened toxicity), considering that an increased blood supply allows for dissipation and control of toxic products and lessened toxicity. Another widely held belief is that apical localization occurs because of decreased aeration in this region (see Best, C A, and Taylor, N B *The Physiological Basis of Medical Practice* Fourth edition, 1169 pp Baltimore Williams & Wilkins, 1945 P 299). Dr Dock considers this to be due to an apical ischemia occurring several hours during the day when the patient is upright. I have not thoroughly investigated the literature regarding these physiologic principles.

If Dr Dock's conclusions are correct—and there is much to recommend them—they should receive wide recognition. Patients with apical tuberculosis should be directed and encouraged to spend more hours flat in bed each day. Studies should be directed toward the determination of how much semirecumbency (with pillows and back rest) can be allowed without interfering with healing of an apical lesion. With this in mind disability in months might be shortened if the patient were appreciably able to increase his daily complete recumbency time.

Another point of interest is the possibility of decreasing the incidence of tuberculosis in contacts by increasing their recumbency time. This would be a hard point to prove, possibly, but speculation might be worth while. Would thirty minutes in a flat position one to three times daily sufficiently increase the apical blood perfusion to prevent implantation with the tubercle bacillus? Would more recumbent time be necessary, or would this procedure have any value? So far, the only preventive measure has been avoidance of contacts and B C G (*Bacillus Calmette-Guérin*) vaccination in children.

Another point of interest is the occasional basal or mid-lung lesion. Could there be an anomalous blood supply in which these areas are relatively avascular?

accompanied by an adequate bibliography and a good index. That curare has a value as an adjuvant to anesthesia and in protecting the patient from injury in shock therapy is well established.

A History of The American Medical Association 1847 to 1947 By Morris Fishbein, M.D. With *The Biographies of the Presidents of the Association* By Walter L. Bierring, M.D. And with *Histories of the Publications, Councils, Bureaus and Other Official Bodies* 4°, cloth, 1226 pp., illustrated Philadelphia W. B. Saunders Company, 1947 \$10.00

In connection with the celebration of the centennial of the American Medical Association, the editor of the *Journal of the American Medical Association* has written a chronological history, setting forth the facts in a correct and orderly manner. Accompanying this text, which covers over five hundred pages, are biographical sketches of the various presidents of the American Medical Association by Dr. Bierring and the recipients of the Distinguished Service Medal. These in general are well written and many facts regarding the earlier presidents have been assembled in this book—material previously difficult of access to medical historians. The volume also contains a record of the councils, bureaus and various publications of the American Medical Association. There is an index of both persons and subjects.

As a reference book this volume is of value. Presumably, the facts are accurately given. Some material, however, is poorly presented, and a considerable number of illustrations are unworthy of both the publisher and the organization sponsoring the volume. Printed on heavy coated stock, the book weighs more than six pounds. It can hardly be called a highly successful venture in publishing. This is all the more surprising in view of the well known firm over whose imprint this volume is issued. Although a "must" item for every medical library throughout the world, the book, because of its format and general appearance, will have little appeal to the average physician.

The Physical Background of Perception. The Waynflete lectures delivered in the College of St. Mary Magdalen, Oxford, in the Hilary Term 1946 By E. D. Adrian, O.M., F.R.S. 8°, cloth, 95 pp., with 21 illustrations. New York Oxford University Press, 1947 \$3.25

Professor E. D. Adrian, a pioneer in the investigation of brain function, summarizes his views on the transmission of the nerve impulse in the peripheral nerves, the sense organs and the brain. Nervous communication appears to be of a relatively simple character, being based on the transmission of repeated waves of activity. These brief disturbances are always made up of the same sequence of physical and chemical changes and, because they are accompanied by small electrical currents, records to show what signals are passing from moment to moment can be made. The electroencephalogram of Berger discloses a 10-per-second rhythm in the brain, associated with the inattentive state, in regions that are playing no part in mental activity because the attention is directed elsewhere. The electrical effects reveal something about the shift of attention but nothing about the way in which the implications of the picture projected on the cortex are recognized.

Thus, many of the problems raised by Adrian have no immediate solution. At present, the picture of mental activity is far from satisfactory.

This book, written in the form of lectures, is a cogent disclosure of present views on brain and mind. No conclusions are reached, and none are justified. The report is one of progress, not a final rendering. As such, Adrian's concise account is highly commendable.

Histopathology of the Ear, Nose and Throat By Andrew A. Eggston, M.D., and Dorothy Wolff, M.A., Ph.D. 4°, cloth, 1080 pp., with 505 illustrations, 28 plates and 9 tables. Baltimore Williams and Wilkins Company, 1947 \$18.00

From the title of this book one would not expect to find such a wealth of information pertaining to the ear, nose and throat. The authors have approached the study of histology and pathology of these structures in a most interesting manner. Anatomy, both gross and applied, as well as physiology, is discussed. The bibliography is complete, so that the reader may refer to original articles for more detailed discussion of any subject that he may be particularly inter-

ested in. The material, concerning subjects for which the authors are well known for their original contributions, is well presented and described.

The book is most unusual in its departure from the style of other works on histopathology because of its being so comprehensive. It will be particularly appreciated by the otolaryngologist, who will not find it necessary to delve through numerous volumes to find the information concerning the ear, nose and throat that he wishes.

The illustrations are good and supportive to the text.

It would be unreasonable to assume that some chapters could not be improved upon in some passages, but this criticism in no way detracts from the over-all value of the content. The volume is particularly recommended to residents, specialists and teachers in otolaryngology. Those who contemplate certification by the national boards will find the book invaluable. No institution with a department of ear, nose and throat should be without it.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Concise Anatomy By Linden F. Edwards, Ph.D., professor of anatomy, Ohio State University. 4° cloth, 548 pp., with 124 illustrations. Philadelphia The Blakiston Company 1947 \$5.50

Hypnotism Today By Leslie M. Lecron, B.A., consulting psychologist and psychotherapist, and Jean Bordeaux, M.A., Ph.D., consulting psychologist and psychotherapist. With a foreword by Milton H. Erickson, M.D., director of psychiatric research, Wayne County Hospital, Eloise, Michigan. 8°, cloth, 278 pp. New York Grune and Stratton, 1947 \$4.00

Signs and Symptoms. Their clinical interpretation Edited by Cyril M. MacBryde, M.D., assistant professor of clinical medicine, Washington University School of Medicine, and assistant physician, Barnes Hospital, St. Louis, Missouri. 4°, cloth, 439 pp., with 74 illustrations and 6 plates. Philadelphia J. B. Lippincott Company, 1947 \$12.00

Rhinoplasty and Restoration of Facial Contour. With special reference to trauma By Jacques W. Mahlman, M.D., clinical professor of plastic reparative surgery and associate attending plastic surgeon, New York Polyclinic Medical School and Hospital, and attending plastic surgeon, Sydenham Hospital, New York City. 8°, cloth, 327 pp., with 214 illustrations. Philadelphia F. A. Davis Company, 1947 \$7.50

Human Gastric Function. An experimental study of a man and his stomach By Stewart Wolf, M.D., assistant professor of medicine, Cornell University Medical College and New York Hospital, and Harold G. Wolff, M.D., associate professor of medicine, Cornell University Medical College and New York Hospital. With a foreword by Walter B. Cannon, M.D. (Oxford Medical Publications). 8°, cloth, 262 pp., with 55 illustrations. New York Oxford University Press, 1947 \$5.00

NOTICES

ANNOUNCEMENT

Dr. Bernard M. Jacobson announces the removal of his office for the practice of internal medicine to 422 Beacon Street, Boston.

PHI DELTA EPSILON LECTURE

Dr. Frank H. Lahey, of the Lahey Clinic, will discuss "Hyperthyroidism and the Antithyroid Agents" at a lecture sponsored by the Tufts Chapter of Phi Delta Epsilon, held in the amphitheater of the Beth Israel Hospital on Wednesday, January 14, at 8:30 p.m. Interested physicians and medical students are cordially invited to attend.

DIARRHEA OF THE NEWBORN*

Its Causes and Prevention

STEWART H. CLIFFORD, M.D.†

BOSTON

A REVOLUTIONARY change in social custom concerning childbirth has occurred during the past decade. Local evidence of this change is afforded by the statistics from the Boston Lying-in Hospital. This hospital delivers about 20 per cent of the infants born in Boston each year. The total number of babies delivered in this institution in 1935 and in 1945 was about the same—4530 and 4685, respectively. In 1935 there were 1015 home deliveries in the outpatient department—in 1945 there were but forty-seven home deliveries, and in 1946 there were none.

The virtual disappearance of home births was not reflected in a corresponding increase in the deliveries on the wards of the hospital. In 1935 there were 2762 ward births, and in 1945 there were 2236.

What, then, happened to the missing 1500 patients? The hospital statistics furnish the answer to this question; these patients demanded private physicians and private ward care, and they were delivered on the private side of the hospital. Richardson House, originally designed to accommodate 900 patients, saw the birth of 753 infants in 1935 and 2401 in 1945.

There can be but one answer to this phenomenon: the public is convinced that the safest place for a mother to have her baby is a maternity hospital. So far as the mother is concerned, statistics have proved the public to be right, for the maternal mortality is reaching an all-time low; it remains to be proved whether the hospital or the home is the safest place for a newborn infant. Evidence submitted from New York City demonstrates that there is at present a persistently upward trend in the death rates from diarrheal disorders in the neonatal group of infants.¹ This increase is due in great

measure to the prevalence of epidemic diarrhea of the newborn.¹

CAUSES OF EPIDEMIC DIARRHEA OF THE NEWBORN

It is significant that the literature on epidemic diarrhea of the newborn has appeared only during the past fifteen years. The appearance of this syndrome as a public-health problem coincides with the shifting of the scene of childbirth from the home to the hospital.

Countless factors have contributed to making the newborn infant in a lying-in institution extremely vulnerable to all types of infection. The combination of an increased birth rate and increased hospital births has led to the mass overcrowding of babies in nurseries. Shortage of personnel in the face of increased demands has resulted in a breakdown in nursery and formula-room technique.

Out of his long experience as a hospital consultant Pollock² observes the tendency of architects and consultants to fail to provide adequate space for nurseries. He found that "all too frequently nurseries are assigned to what might be designated as left-over space and their size is determined by the number of bassinets that can be crowded in without any regard to spacing or the aisles between them."

A review of the literature clearly indicates that the syndrome described as epidemic diarrhea of the newborn is not a pathologic entity but a miscellaneous group of cases of various etiologies, known and unknown, bound together by a common symptom—diarrhea.

The reported epidemics can be divided into three groups. In the first, evidence of a bacterial origin is present, although the organisms discovered frequently belong to groups not ordinarily considered pathogenic, the infecting agent apparently enters the nursery via an adult carrier and reaches the infant by the fecal-oral route through a break in the nursery or formula room technique. The second group

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1947.
From the Boston Lying-in Hospital and the Department of Obstetrics and Pediatrics, Harvard Medical School.

†Associate in pediatrics, Harvard Medical School; pediatrician, Boston Lying-in Hospital; physician and chief of Premature Service, Infants and Children's Hospital.

includes the epidemics in which a virus etiology has been proved or strongly suspected with the backing of certain presumptive evidence. The large and controversial third group comprises outbreaks in which etiologic studies on the stools have failed to demonstrate an inciting agent.

EPIDEMICS OF BACTERIAL ORIGIN

A significant investigation into the cause of recurrent outbreaks of epidemic diarrhea of the newborn in a Kansas Hospital has been reported by Ensign and Hunter,³ whose approach was based on a knowledge of the method of spread of the infection rather than on a bacteriologic search for specific organisms. From June to October, 1945, six outbreaks of diarrhea had occurred in the hospital nursery, during the same period more than 400 cases of diarrhea in adults had occurred in the community. Prior to each of five hospital outbreaks, one mother or nurse on the obstetric floor had developed the disease. In the sixth outbreak the mother had had the disease shortly before entering the hospital. In every case in which the mother had the disease her infant developed it. The nurseries were crowded and there was a shortage of personnel. The authors reasoned as follows:

The outbreaks could be easily explained on the basis of secondary infection from infected mothers or nurses if we keep in mind a well-known fact in the epidemiology of gastrointestinal disease, namely, that apparently healthy persons who have ingested organisms are carriers of those organisms until they are eliminated from the alimentary canal. These organisms may be eliminated in one or two days. Nevertheless, until they are eliminated, persons harboring them are temporary carriers capable of passing the infection on to others. The only condition which could result in a large group of temporary carriers is a recent ingestion of contaminated food or water.

Their investigations proved that the milk supply of the entire community was grossly contaminated with *Bacillus pyocyaneus* (*Pseudomonas aeruginosa*) at the dairy and that the milk was then not sufficiently pasteurized. Bacterial counts on the milk disclosed over 3,000,000 organisms per cubic centimeter. *Ps. aeruginosa* was isolated from all infants' stools cultured, from autopsy material, from nurses' stools and from the milk supply.

McClure⁴ reports four different hospital epidemics of diarrhea of the newborn in the Province of Ontario. In Hospital "A" two outbreaks occurred. In the first of 62 infants, 26 became ill, and 3 died. Hemolytic *Escherichia coli* was found in the stool cultures of 14 of 16 infants and also in the nursery supervisor's stool culture. In the next outbreak, which involved 31 infants with 7 deaths, eight stool cultures were made, and seven showed hemolytic *Esch. coli*. Stool cultures of 16 normal infants were negative. Cultures in 4 of 17 nurses showed hemolytic *Esch. coli*. The milk formula showed a high bacterial count, with nonhemolytic *Esch. coli*. Cultures from the top of the common bathing table showed hemolytic *Esch. coli*. Six of the hemolytic

Esch. coli strains from the infants, bathing table and a night nurse were identical by sugar reactions. Another strain from an infant and one from a nurse were identical.

In Hospital "B" the epidemic was dated from the time a mother and her infant developed diarrhea. Seven infants became ill, and 1 died. Subsequently, stool cultures on 12 healthy babies in the nursery revealed hemolytic *Esch. coli* in 7. In Hospital "C" 12 infants developed diarrhea, and an abundant growth of hemolytic *Esch. coli* was obtained from evaporated-milk formula and nipple jars. In Hospital "D" a severe epidemic occurred, 18 infants had the disease, and 12 died. Hemolytic *Esch. coli* were obtained from the stools of 8 of 11 sick infants and from 2 of 18 healthy infants. In their investigation the authors found the nursing technic in all these hospitals very faulty—the diapers were rinsed in the same nursery sink in which the formula bottles were subsequently warmed. Milk was stored on the wards in quart stock bottles from which the individual bottles were filled at feeding time.

Baker⁵ reported three epidemics of diarrhea of the newborn occurring between 1935 and 1938 in one New York Hospital. The first outbreak involved 59 infants in the obstetric nurseries. Various organisms were grown on stool culture but not consistently enough to be thought significant. These organisms included *Esch. coli mutabile*, hemolytic *Staphylococcus aureus*, *Staph. albus*, *Bacillus subtilis*, *Esch. coli*, alpha-hemolytic streptococcus, gamma-hemolytic streptococcus and *Aerobacter aerogenes*. The second outbreak involved 13 premature infants. Cultures of the stools of 9 patients revealed *Esch. coli mutabile* or hemolytic *Esch. coli* organisms, which some workers have regarded as pathogenic. The author quotes Dulaney, who found *Esch. coli mutabile* in the stools of 67 per cent of patients in an epidemic of diarrhea of the newborn. In the third outbreak involving 13 infants, no suspicious stool organisms were isolated.

McKinlay⁶ described an epidemic involving 6 infants with 2 deaths apparently caused by an organism of the *Salmonella* group. She found a nurse as the probable carrier of the infection. Bloxson⁷ reported an epidemic of infectious enteritis in Houston, Texas, with a mortality of 50 per cent. Stool cultures in 18 cases revealed organisms of the *Salmonella* group in 5. Abramson et al.⁸ discussed an epidemic of diarrhea in the newborn due to *Salmonella* infection. Cummings⁹ observed a nursery outbreak in Michigan caused by *Salmonella Panama*, with 12 deaths. Diarrhea had been rampant six months prior to the epidemic studied and had occurred sporadically in the interval. *S. Panama* was recovered from the stools of a graduate nurse, a nurse's aide and a maid.

Jampolis and his colleagues¹⁰ have reported an epidemic due to *Klebsiella pneumoniae* (*Bacillus*

murcus capsulatus) This infection was traced to 3 nursery maids

Schwenther¹¹ described an epidemic of diarrhea from Baltimore in which there were 21 deaths. *Bacillus dyspar* was recovered from the stools of 36 infants

Wheeler and Foley¹² isolated Lancefield Group D streptococci in an outbreak in Boston, with epidemiologic and clinical studies that suggested respiratory or air-borne transmission. The authors make the important observation that Group D streptococci may be of pathogenic significance in infants. They point out that beta characteristics are not specific for this group of streptococci. Alpha, beta, and gamma strains were encountered in all serologic types of Group D organisms — "a fact which invalidates many earlier and more extensive attempts to determine the incidence of the various serologic groups of streptococci in normal infants."

The preceding review of recorded outbreaks of epidemic diarrhea demonstrates several points: the epidemics may be caused by a diversity of organisms, the newborn infant appears to be very susceptible to infection with organisms not ordinarily considered pathogenic, any infant fed milk or fluid from a bottle is peculiarly vulnerable to infection because the same person who feeds him and handles the nipples also handles the diapers and the infant's excreta, and it is well known that efficient scrubbing is required to free the hands and fingernails of bacteria of fecal origin, and many of the epidemics can be traced to carriers in the nursery personnel, infection by this fecal-oral route constituting ample evidence of faulty nursing technique.

EPIDEMICS OF VIRUS ETIOLOGY

A virus etiology for certain outbreaks of diarrhea in the newborn has been suspected from the first. However, the evidence for a virus infection has been chiefly negative, many epidemics having received most careful epidemiologic and bacteriologic investigations without the discovery of a specific etiologic organism. The infants in these outbreaks frequently exhibit a normal or lowered white-cell count and fail to respond to chemotherapy.

Lyon and Folkom¹³ described three epidemics in 1926, 1934 and 1938 that suggest the virus of influenza as a possible etiologic agent, since at the time of each epidemic clinical influenza infection was present in the community.

In 1943 Campbell¹⁴ reported from Melbourne outbreaks occurring in three hospitals at the same time that epidemic cases of so-called "gastric flu" were common in the city. In 1944 a severe epidemic of diarrhea of unknown etiology in the newborn was observed in Philadelphia by High, Anderson and Nelson,¹⁵ occurring at the same time as an epidemic of diarrhea, nausea and vomiting of unknown cause in adults.

The first positive evidence that a filterable virus was a cause of certain epidemics of diarrhea of the newborn was submitted by Light and Hodes.¹⁶ Two epidemics were studied in 1941, and stool filtrates tested in a variety of small animals, with negative results. In 1942 two epidemics in Baltimore and two in Washington were studied. In each of the four epidemics pooled stools, Seitz-filtered in three and unfiltered in one, were given nasally to young calves. In two to five days all the animals developed a bloody, mucoid diarrhea that lasted an average of three weeks. Successive calf passages were easily made with each of the four strains. Cross-immunity studies indicated that the four strains represented a single agent.

After recovery the calves had developed immunity and large doses of active material failed to cause disease. Serums obtained from 6 infants after convalescence conferred complete or partial protection against the nasal injection of active material. The virus was not inactivated until the material had been boiled for ten minutes or exposed to a temperature of 80°C (170°F) for an hour.

Cummings⁹ is convinced that he was able to recover, in an epidemic of diarrhea of the newborn, a filterable agent of the type described by Light and Hodes, although he was unable to maintain the potency of this agent beyond the fifth calf transfer. This epidemic involved 22 babies. Nose, throat and stool specimens were obtained free from bacterial pathogens. Pooled material was tested for viruses in mice, monkeys, guinea pigs, chicks, cotton rats, chick embryos, hamsters, newborn pigs and newborn calves. All the animals or mediums reacted negatively except the calves.

In October 1943 Buddingh and Dodd¹⁷ observed one of a pair of twins to have stomatitis and diarrhea. Within the next two weeks and in spite of strict isolation precautions 16 of 30 infants in the nursery developed diarrhea, with a mild stomatitis in 10. In contrast with other epidemics of diarrhea of the newborn this outbreak was relatively mild, with no fatal cases. With an inoculum of stools obtained in this epidemic the authors were able to produce lesions on the scarified cornea of rabbits. The agent was readily filterable through Berkefeld V candles. Strains of the agent were maintained for as many as forty-five serial passages. Immunity developed in the rabbit eye in a period of three weeks. Serum obtained from 12 patients during the acute disease produced positive results when mixed with the virus, similar mixtures using serum obtained during convalescence caused no lesions. Attempts to propagate the virus in other animals or in the developing chick embryo were unsuccessful. The filterable agent has been isolated by Buddingh¹⁸ from stools obtained in epidemics in Nashville, Memphis, Cincinnati and Boston. Cross-immunity has been demonstrated between all strains regardless of whether the death rate in an epidemic was 0 or over 50 per cent. It has not been possible

to determine whether the viruses isolated by Light and Buddingh are the same. It seems probable that a virus is the usual etiologic agent in epidemic diarrhea of the newborn, but, as in encephalitis, different viruses may be concerned in different epidemics.¹¹

Cummings⁹ and the group studying diarrhea and enteritis in Michigan encountered an epidemic of diarrhea in the premature section of a children's hospital. Because newborn calves were not available at the time, the material obtained was tested on smaller animals with negative results and on the rabbit's cornea after the method of Buddingh and Dodd. The Seitz filtrates of pools of infants' stools gave positive eye reactions. However, subsequent experience with serial passages of corneal material led the group to conclude that the reaction was erratic if not nonspecific. They tested a large number of rabbit corneas with trauma, trauma and alundum, stools and mouth washings from normal infants and various bacteria and found it possible with all these specimens or technics to produce what they considered to be typical positive eye reactions as described by Buddingh and Dodd.

Cummings's conclusion that Buddingh's rabbit-eye scarification test is not specific for the virus of epidemic diarrhea is a great disappointment to all workers in the field. This simple method of proving a virus etiology in an epidemic under investigation had been expected to clarify much of the present confusion surrounding this syndrome. At present the test must be shelved until other investigators prove its exact status.

The lack of a relatively simple technic to identify the virus of this disease is the greatest handicap to further progress. Both Light and Hodes and Cummings agree that the virus can be grown and studied in newborn calves. This method is of limited usefulness in actual practice. Light and Hodes have reported but one experiment based on four outbreaks, whereas Cummings, with his elaborate study group financed jointly by the Kellogg Foundation and the Michigan Department of Health Laboratory in a four-year study of many epidemics of diarrhea, has only reported the use of calves in testing the material from one epidemic.

Since we cannot at the moment accept the epidemics reported by Buddingh and Dodd as having a proved virus etiology, the only positive evidence is found in the four epidemics reported by Light and Hodes and the one reported by Cummings.

EPIDEMICS NOT ASSOCIATED WITH THE USUAL BACTERIAL PATHOGENS

The epidemics of diarrhea in the newborn in which no virus etiology has been demonstrated and in which none of the usual bacterial pathogens have been found constitute by far the largest group reported in the public press and in the medical literature and by public-health officials studying the problem.

An epidemic involving 32 infants with a high mortality was described in 1936 by Barenberg, Levy and Grand¹⁹ in which no specific etiology could be found but in which the authors suspected that either a virus or certain toxins of the colon bacillus were responsible. Rice et al.²⁰ analyzed eleven outbreaks of highly fatal diarrhea in New York City between 1934 and 1936 in which no inciting agent could be discovered. In a subsequent paper in 1939 Frant and Abramson²¹ confirm the negative pathological and bacteriologic findings and point out that diarrhea of the newborn epidemiologically exhibits the characteristics of a highly virulent communicable disease. They suggest that these infections were not reduced because of certain inherent deficiencies in present methods of obstetric, pediatric and nursing care of the newborn — the modern mass care of newborn babies in open nurseries may even promote the rapid spread of infection.

Outbreaks occurred in 1940 in three widely separated English cities with a case mortality of 29 per cent. No specific etiology could be discovered, but Ormiston²² believed that the cause might be a virus or systemic infection or a general metabolic disturbance leading to the proliferation of any pathogenic or potentially pathogenic organism that happens to be present in the bowel.

Epidemic diarrhea occurred in San Francisco in 1942 and 1943, and Geiger and Sappington²³ reported 324 cases with 45 deaths. Although no specific etiology was found there was marked overcrowding in almost every nursery, as well as lowered standards of nursing care.

Weymuller, Beck and Ittner²⁴ describe an outbreak of epidemic diarrhea involving 19 infants with no deaths. A very carefully thought out prophylactic technic had been in successful operation from 1937 to 1945, when, because of a shortage of nurses, the technic was necessarily violated, and the authors believe that the epidemic was the result.

Rubenstein and Foley²⁵ reviewed nineteen outbreaks of epidemic diarrhea of the newborn of unknown etiology reported to the Massachusetts Department of Public Health from 1935 to 1945. In all, 258 cases were reported, and 85 patients died. Their investigations revealed almost unbelievable breaks in nursing and formula-making technic. Although the practice was in direct violation of existing regulations, 7 nurseries used a common rectal thermometer. The thermometers were supposedly sterilized by soaking in a bichloride or alcohol solution. Bacterial counts on samples of one of these thermometer dips revealed 7,000,000 viable microorganisms per cubic centimeter, mostly *Esch coli*. A sample of dip from another nursery revealed 44,000 organisms, the majority being *Esch coli*, *Proteus vulgaris* and *Staph albus*. Several nurseries used common oil bottles instead of the recommended individual cups. In many nurseries nurses dip their hands in so-called "sterilizing" solutions. Bacterial

counts on two of these dips, one bicliloride and one alcohol, revealed 75,000 and 150,000 organisms per cubic centimeter, including *Staph aureus*, *Esch coli*, alpha streptococcus, Lancefield Group D streptococcus and *B subtilis*.

Adequate space was available in only 3 nurseries, and the nursery staffs were considered adequate in only 3. In 6 of the 10 hospitals formula preparation was not adequately supervised. Samples of formulas from several nurseries gave bacterial counts of 9500, 32,000 and 396,000 per cubic centimeter, the identified organisms being alpha streptococcus, Lancefield Group D streptococcus, *Esch coli*, *Staph. albus*, *Pr vulgaris* and *B subtilis*. Examinations of nipples revealed the presence of large numbers of organisms. One supposedly sterile nipple and one funnel produced a pure culture of *Staph aureus*.

Cummings⁹ and his study group made similar discoveries regarding nursery practice in Michigan. In investigating a number of outbreaks of neonatal diarrhea with stool cultures that were negative for the usual pathogenic organisms, Cummings became interested in the variety of organisms that were identified and he began to speculate on their etiologic significance. The bacteria isolated included coagulase-positive staphylococci, hemolytic streptococci, various strains of Proteus, *Shigella alcalescens*, *Bacterium alcaligenes* (*Alkaligenes faecalis*) and various coliform organisms. These organisms were also routinely recovered from the various supplies, equipment and solutions of the nurseries. In one nursery *Bact alcaligenes* was isolated from twenty-four stool specimens, fifteen meconium specimens, one infant nose speculum, three nurse stool specimens and three course's-side stool specimens. It was also isolated from nursery basins, enema solutions, subcutaneous saline solutions, soap solutions, table-tops and handbrushes. The conclusion was as follows:

It has gradually become the opinion of the study group that this type of outbreak is due to massive bacterial contamination with organisms usually considered to be of low or absent pathogenicity together with a complete absence of the usual nursery techniques. It is felt that filth in the nursery is the principal contributing factor.

From Rochester, New York, comes a report by Lembecke, Quinlivan and Orchard¹⁰ of two outbreaks of epidemic diarrhea of the newborn that occurred within a four-month period of 1942. The epidemics were controlled by studies on the mode of transmission. The first outbreak affected 28 of the total of 50 infants, with 3 deaths, and was believed to have been transmitted by contaminated rubber nipples and formulas and to a lesser extent by indirect contact. The nurseries were understaffed, babies were diapered before being fed, the band washing was very perfunctory in cold or tepid water, with very little soap. The rubber nipples were boiled for less than twenty minutes, with some of the nipples float-

ing on the surface, and formulas were inadequately sterilized. Four formula cultures and twelve nipple cultures revealed organisms of the coloco bacillus group, presumably of fecal origin. In the second epidemic breast-fed infants were chiefly attacked. Again, infants were diapered prior to feeding, and there was faulty technic in both hand and breast washing.

It is thus readily seen that the reported outbreaks of epidemic diarrhea of the newborn in which no etiology could be established can also be subdivided into two groups. The first consists of outbreaks in nurseries with excellent technics where careful investigation of the affected patients and of their environment by both bacteriologic and epidemiologic studies fail to reveal an etiologic agent, in these outbreaks the negative evidence suggests a virus etiology. In the second and by far the largest group, investigations by trained epidemiologists and bacteriologists failed to reveal a specific organism, but such atrocious nursery and formula-room technic was uncovered that infection with anything was possible. As suggested above the epidemic may even have resulted from massive bacterial contamination with organisms of low or absent pathogenicity.

PREVENTION

It is evident that diarrhea of the newborn can be caused by a variety of infections. When the services of trained epidemiologists and bacteriologists with adequate laboratory facilities are available, investigation of an epidemic may quickly reveal a specific etiologic agent. When these facilities are not available or if available are not called on, an epidemic may well pass without etiologic diagnosis. Recorded experiences have reported *Pseudomonas aeruginosa*, *Esch. coli mutabile*, hemolytic *Esch. coli*, organisms of the Salmonella group, *K pneumoniae*, *S dysenteriae* (Sonne) and Lancefield Group D streptococcus as having been the probable cause of certain epidemics of newborn diarrhea. From the point of view of prevention the presence of these organisms indicates a breakdown in nursery technic that permits carrier-fecal-oral infection of the newborn.

There can be little doubt that virus infection can produce epidemic diarrhea in the newborn. There is suggestive evidence that certain viruses, presumed to be the agent of widespread disease in the community, may also be the cause of coexisting epidemic diarrhea in the local nurseries. There is positive evidence that five epidemics have been caused by a specific virus. In other epidemics there is suggestive evidence for a specific virus etiology in the tendency of diarrhea to spread in the pediatric wards after the baby from a nursery epidemic is admitted for treatment, in contrast to the lack of spread when the infant's infecting organism belongs to the Salmonella or dysentery group. In the absence of a practical method of demonstrating the presence of

a virus in a given epidemic it is impossible to know how many or how few epidemics now classed as of unknown etiology are of specific virus etiology

The discovery of a practical method to identify and study the specific virus of epidemic diarrhea would be one of the greatest advances in modern pediatrics. It is quite apparent that such a discovery would be of inestimable value in controlling the occasional outbreak of this disease in the obstetric nursery of healthy infants. What is not so generally appreciated is that this disease is not confined to newborn nurseries and that it is endemic in infants' hospitals, where it constitutes a great and perennial problem, the solution of which may well hinge on the discovery of such a method of study.

The etiologic importance of a specific virus in certain outbreaks cannot be overemphasized but at the same time it is well to point out that before negative evidence of a virus etiology can be considered, the epidemiologic and bacteriologic investigations must satisfy the highest standards. Whenever trained public-health officials have investigated numerous epidemics of supposedly unknown etiology, whether the investigations took place in Massachusetts, Michigan or New York, the investigators have uncovered such unbelievably poor nursery and formula-making technic that it has been unnecessary to fall back on an unknown virus to explain the epidemic.

Physicians who have the responsibility of caring for newborn infants in the large and small hospitals throughout the land must set about preventing epidemics of diarrhea whose causes are known. Care of the newborn must be altered so that a baby is not fed a formula containing 396,000 bacteria per cubic centimeter from a nipple covered with a pure culture of staphylococci with hands bearing *Salmonella*. The nursery staff must be as alert to the dangers of diarrhea in the newborn as the obstetric staff is to the dangers of the hemolytic streptococcus infection in the mother. No nurse with scarlet fever would think of going into the delivery room, and yet a colleague investigating an outbreak of diarrhea in a distant city found a nurse who stated that just prior to the outbreak she had had such a severe diarrhea that she had been forced to spend more time out of the nursery than in it. Perhaps, when these glaring breaks in technic have been controlled, the protection thus afforded may well block the spread of virus infection as well.

The long-term protection of mothers and newborn infants in lying-in institutions demands an extensive national program of new hospital construction. In some hospitals in this country mothers are placed on cots in corridors, and the average stay in these hospitals for mother and child is forty-eight hours. In either new construction or the remodeling of old hospitals primary attention must be given to the needs of the newborn infant. Ideally, each infant should have a private room, or a mother and her

infant should share the same room. Certainly, the massing of infants in one nursery should be avoided. The present compromise suggested is that the maximum number of babies assigned to one nursery unit should be the number from six to twelve that can be attended by one nurse.

The following basic principles underlying the control of infection in newborn nurseries that must be satisfied by a successful nursery technic are relatively simple.

Block air-borne infection, both that acquired at short range by droplet transmission and that acquired from pathogenic organisms diffusely distributed throughout the air

The requirement that each infant in the nursery be provided with 300 cubic feet of air space, or 30 square feet of floor space,²⁷ is an attempt to protect the infant from air-borne infection by the dilution factor. Many existing hospitals would find it a physical impossibility to satisfy this requirement. The same dilution factor could be provided an infant in half the floor space if the air-circulation rate were doubled. Chapple²⁸ has reported that recent experience has demonstrated that the air in the nurseries can be sterilized by ultraviolet radiation and by the evaporation of propylene glycol to a strength of 1/5,000,000 in the air (a continuous evaporation of approximately 0.01 cc of propylene glycol per cubic foot in a still nursery). The bacterial count in the air can be reduced by the use of an oil film on the floor and by oil-impregnated blankets and linen. It should be apparent that 30 square feet per infant should not be accepted as a fixed requirement when other solutions may be even more efficient.

The control of droplet infection is a more difficult matter, many believe that the ordinary mask is most inefficient. If masks are to be relied on they should be of the deflection type or made of thick layers of nonabsorbent cotton.

For nurseries with limited available space, for isolation nurseries and for premature-infant nurseries an incubator of the Chapple type may be the solution. In this incubator the infant is surrounded by conditioned fresh air drawn directly from outdoors and is further protected from all droplet infection through being completely inclosed in the incubator.

Block infection acquired from the ingestion of pathogenic organisms contained in food or fluid

This problem is the easiest of all to solve through the terminal unit sterilization of the formula or fluid in the bottle, with the nipple attached and covered.

Block infections acquired from physical contact between the infant and infected personnel or material

Cummings⁹ and his group were able to prevent this type of infection through expert nursing supervision, adequate nursing personnel, infection control among nursery personnel and mothers, carrier control among nurses and mothers, isolation of infected infants, hand technic, sterile supplies and visitor control.

One physician should be appointed as chief of the nursery service with the responsibility and authority for maintaining the standards for the care of all newborn infants, public and private.

It is fortunate that each hospital is not forced to work out for itself the details of standards and recommendations for the nursery care of their full-term and premature infants. The Children's Bureau, in co-operation with an advisory committee of obstetricians and pediatricians and with the help of the Committee on the Fetus and Newborn Infant of the American Academy of Pediatrics, have prepared and published standards and recommendations¹⁰ that, if adopted so far as possible by every hospital attempting infant care, would satisfy the basic principles mentioned and go a long way toward removing the hazard of epidemic diarrhea in the newborn.

All who have been given the grave responsibility of the newborn nurseries in lying-in institutions know that sooner or later, for one reason or another, one or more of their infants may develop diarrhea. The entire literature is in agreement regarding how this situation should be handled.^{11, 12, 13, 14, 15, 16} If 1 infant develops diarrhea he should be instantly isolated in an isolation nursery until the significance of the situation can be judged. Should 2 infants from the same nursery develop diarrhea, both babies must be isolated and the nursery quarantined until all contacts have been discharged and the nursery cleaned and made ready for new admissions. With the declaration of the quarantine a mobile nursery should be set up in an available room into which all freshly delivered patients shall be admitted. If 3 infants from the same nursery develop diarrhea the syndrome of epidemic diarrhea of the newborn is assumed to be present, and the situation instantly reported to the board of health.

Strict adherence to this program may well limit a potential epidemic to 1 or 2 cases. The literature stresses the fact that it is disastrous to temporize with this situation.

Should a real outbreak of epidemic diarrhea occur, reported experience insists that the only way to stop the outbreak is to shut down the entire obstetric unit to all admissions until all patients are discharged.

SUMMARY

The emergence of epidemic diarrhea in the newborn as a public-health problem coincides with the transfer of the scene of childbirth from the home to

the hospital. Hospitals have been unprepared for this migration, and the mass crowding of infants in nurseries, in addition to the shortage of personnel, has produced conditions favorable for the spread of infection. There is a national need for more obstetric beds and for more nurseries, each to be limited to 8 to 12 newborn infants.

A specific virus etiology for five epidemics has been proved. This virus is probably the cause of many other outbreaks. There is great need for a practical method of demonstrating a possible virus etiology during the progress of an epidemic of diarrhea. It is dangerous to assume a virus etiology for an epidemic on the basis of negative evidence unless the epidemiologic and bacteriologic investigation has been conducted by experts. Specific measures to control or prevent virus diarrhea can be expected to follow the discovery of practical methods to identify and study the virus.

Many epidemics of diarrhea in the newborn have been traced to a variety of pathogenic organisms that could only reach the infant by the fecal-oral route. In the greatest number of epidemics the patients have had none of the usual bacterial organisms in the stools, and yet in a large percentage of these outbreaks trained investigators have found evidence of gross breaks in nursery technic.

Without waiting for the results on future virus research the first obligation is to block all routes by which the infant can acquire bacterial infection in the nursery through a strict application of known nursery and formula-room technics. It is even conceivable that strict technic may block the spread of virus as well as bacterial organisms.

Many large hospitals caring for thousands of babies each year have demonstrated that a strict nursery and formula-room technic can, in spite of personnel shortages and crowding, protect the newborn population from outbreaks of epidemic diarrhea.

AN UNUSUAL CASE OF ACUTE INFECTIVE POLYNEURITIS WITH VISCERAL LESIONS*

FREDERIC PARKER, JR, MD,† AND RAYMOND D ADAMS, MD‡

BOSTON

THE terms "acute febrile polyneuritis," "acute infectious polyneuritis," "infectious neuronitis" and "Guillain-Barré syndrome" are commonly used to designate a class of diseases that are characterized by the acute onset of an ascending flaccid motor paralysis, with loss of tendon reflexes and sensory changes in the extremities, and by elevation of the spinal-fluid protein without pleocytosis. Facial diplegia occurs in some cases and, less often, bulbar paralysis. Paralysis of respiratory muscles results in death in 10 to 40 per cent of cases, and recovery is usually complete in the survivors. The cause of the disease is unknown. Although attempts to isolate a filterable virus or a bacterial neurotoxin have been unsuccessful, an infectious etiology has been predicated because of the usual antecedent respiratory or gastrointestinal infection, the acute febrile course and the nature of the pathological changes.

At the Boston City Hospital we have encountered 3 or 4 cases of acute infective polyneuritis each year. The clinical features of 26 of these cases was the subject of a recent review by Forster, Brown and Merritt.¹ Owing to the high mortality (42 per cent) an opportunity has been afforded to conduct post-mortem examinations in several of them. One in particular excited our interest because of the association of polyneuritis and jaundice.

It is reported in detail because of the rarity of such cases in the medical literature.

CASE REPORTS

CASE 1 The patient (BCH A44-164), a 28-year-old man, entered the hospital on February 2, 1944, because of dyspnea, orthopnea, cough and ankle edema. These symptoms had developed gradually for the previous several years and progressed in the preceding few weeks to the point where he was incapacitated for work.

At the age of 12 years, the patient had had arthritis involving both ankles and causing a deformity of the feet. In 1936, when he was 20 years of age, the deformity had been corrected by a transplantation of the extensor tendons. At that time a cardiac murmur was discovered, and for the next year he was treated by continuous bed rest for suspected rheumatic fever.

Physical examination revealed the patient to be somewhat distressed by flatulence, which was only partially relieved by frequent eructations of gas. He was orthopneic. The heart was moderately enlarged, and there was a systolic thrill over the apex. Diastolic and systolic murmurs were heard at both the base and the apex of the heart. The apical systolic murmur was harsh and blowing, and the diastolic murmur was low, rumbling and presystolic in time. The liver and spleen were not palpable.

The temperature was 98.6°F, the pulse 88, and the respirations 30. The blood pressure was 148/50.

Examination of the blood disclosed a hemoglobin of 86 per cent and a white-cell count of 16,800 that fell to normal thereafter. The differential count was within normal limits. The corrected sedimentation rate was 0.45 mm per minute. The blood nonprotein nitrogen was 65 mg per 100 cc. on admission and later 36 and 31 mg. The urine had a specific gravity of 1.032, the first three specimens gave a +++ test for albumin and the sediment contained a few red and white cells, but later specimens were normal. The vital capacity was 1.9 liters. Four electrocardiograms revealed lengthened PR interval of 0.30 to 0.38, the T waves were low, with a slightly high origin, in Lead 1 and diphasic in Leads 2, 3 and 4. These records were interpreted as "consistent with active myocardial involvement."

The patient was digitalized, and all the symptoms disappeared. He was discharged on February 25, with instructions to continue taking digitalis.

*From the Mallory Institute of Pathology and the Neurological Unit, Boston City Hospital, and the Department of Neurology, Harvard Medical School.

†Associate professor of pathology, Harvard Medical School, pathologist-in-chief, Mallory Institute of Pathology, Boston City Hospital.

‡Assistant professor of neurology, Harvard Medical School, lecturer in neurology, Tufts College Medical School, visiting neurologist and neuropathologist, Boston City Hospital, neurologist, Joseph H. Pratt Diagnostic Hospital.

On the 2nd day after discharge, he developed a mild discomfort in the epigastrium that rapidly increased in severity radiating to both sides of the chest anteriorly. The pain was not affected by breathing, by food or by belladonna. Repeated gaseous eructations afforded some relief. The patient was readmitted on February 28.

Physical examination showed that the patient was considerably distressed by the abdominal pain. He was oriented and rational. There were numerous small nontender axillary and inguinal lymph nodes. The heart was moderately enlarged, and the murmurs were unchanged. No signs of cardiac decompensation were present. The liver and spleen were

During the first 5 days in the hospital the abdominal pain became much less severe. The surgical consultant was of the opinion that there were no signs of peritoneal irritation or intestinal obstruction. On the 6th hospital day the patient had a sore throat, but the temperature was normal. The white-cell count at that time was 30,200 with 60.5 per cent neutrophils (52.5 per cent adult and 8 per cent band forms), 0.5 per cent eosinophils, 16 per cent small lymphocytes, 9 per cent atypical lymphocytes, 1 per cent large lymphocytes, 9 per cent young lymphocytes and 4 per cent monocytes. The blood smear was thought to be consistent with a diagnosis of infectious mononucleosis. The corrected sedimenta-

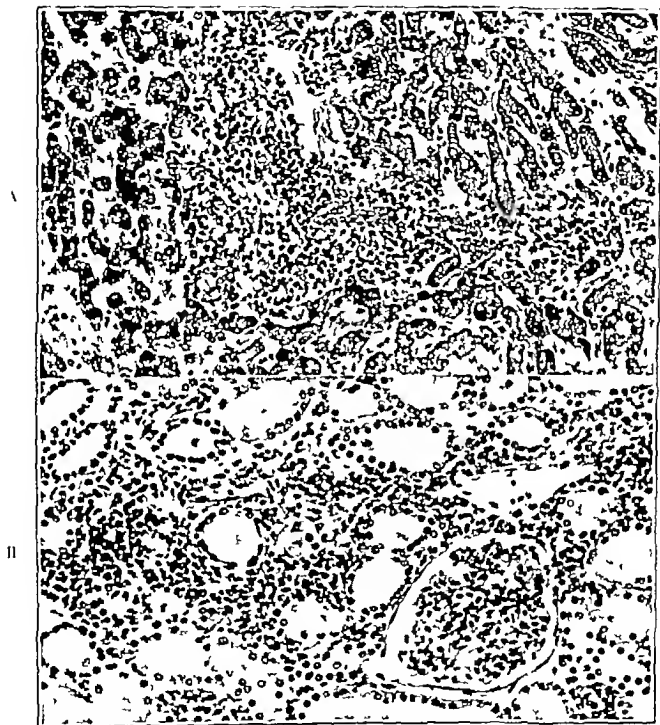

FIGURE 1. A Shows a Papanicolaou's Methylene Blue Stain of Portal Area of Liver to Demonstrate Infiltration of Lymphocytes, Plasma Cells and Unidentified Mononuclear Cells. B Illustrates a Papanicolaou's Methylene Blue Stain of the Kidney Showing Interstitial Infiltration of Lymphocytes, Plasma Cells and Rare Eosinophils.

not palpable. Neurologic examination revealed no abnormal findings.

The temperature was 98°F, the pulse 100 and the blood pressure 135/40.

Examination of the blood revealed a hemoglobin of 88 per cent and a white-cell count of 6450 with 82 per cent neutrophils, 9 per cent lymphocytes and 10 per cent monocytes. The blood Hinton reaction was negative. The blood nonprotein nitrogen was 50 mg. per 100 cc. on entry and later normal. Examination of the urine was negative. An electrocardiogram showed sinoauricular tachycardia, incomplete auriculoventricular block and a further alteration of T waves — all consistent with a diagnosis of active myocardial involvement. Blood cultures were sterile.

tion rate was 0.8 mm. per minute. Tests for heterophil antibodies were negative at that time and on two subsequent occasions.

On the 12th hospital day the patient began to have a sensation of tingling like "pins and needles" in the feet and hands and a numbness of the trunk. When the toes touched the foot of the bed they felt as if charged with electricity. On the 14th hospital day he became slightly jaundiced. At that time, the icteric index was 25, the cephalin flocculation test ++++ and the prothrombin time 60 per cent. In succeeding days the paresthesias continued and prolonged muscle weakness appeared. The neurologic consultant noted mental confusion, a peripheral type of facial weakness on the right and a flaccid weakness of all four extremities with the

legs affected more than the arms, loss of tendon reflexes, but active abdominal and flexor plantar reflexes, exquisite muscle tenderness and impairment of all forms of sensation in the distal parts of the lower extremities. On the night of the 16th hospital day, the patient had a "nightmare" and was incontinent of urine. The icteric index was 10, the carbon dioxide combining power was 39 milliequiv per liter, and the blood sugar 123 and the blood nonprotein nitrogen 63 mg per 100 cc. The white-cell count was 35,100, with 59 per cent adult neutrophils and 16.5 per cent band forms, 0.5 per cent basophils, 7.5 per cent small lymphocytes, 2.5 per cent atypical lymphocytes, 1.5 per cent large lymphocytes, 4.5 per cent young lymphocytes, 4.0 per cent monocytes, 1.5 per cent young monocytes, 2.0 per cent young plasma cells and 0.5 per cent metamyelocytes. The cerebrospinal-

the anterior one was calcified. The chordae tendineae were shortened and thickened, as were the papillary muscles. The capacity of the left ventricle was twice normal, and the left ventricular wall was symmetrically hypertrophied. The endocardium was smooth except for an area of roughening and calcification, 2.5 cm in diameter, beneath the aortic valve. The cusps of the aortic valve were thickened and partially calcified, and their free edges were rolled and shortened. There was slight widening of the commissures between the right and left posterior cusps. The coronary ostia and arteries were patent. In the first portion of the aorta, for a distance of about 3.5 cm, the intima was uneven and discolored. Elsewhere in the aorta subintimal streaks of atheroma were visible. The tricuspid valve measured 11.5 cm, the pulmonary valve 7.7 cm, the mitral valve 10.2 cm and the

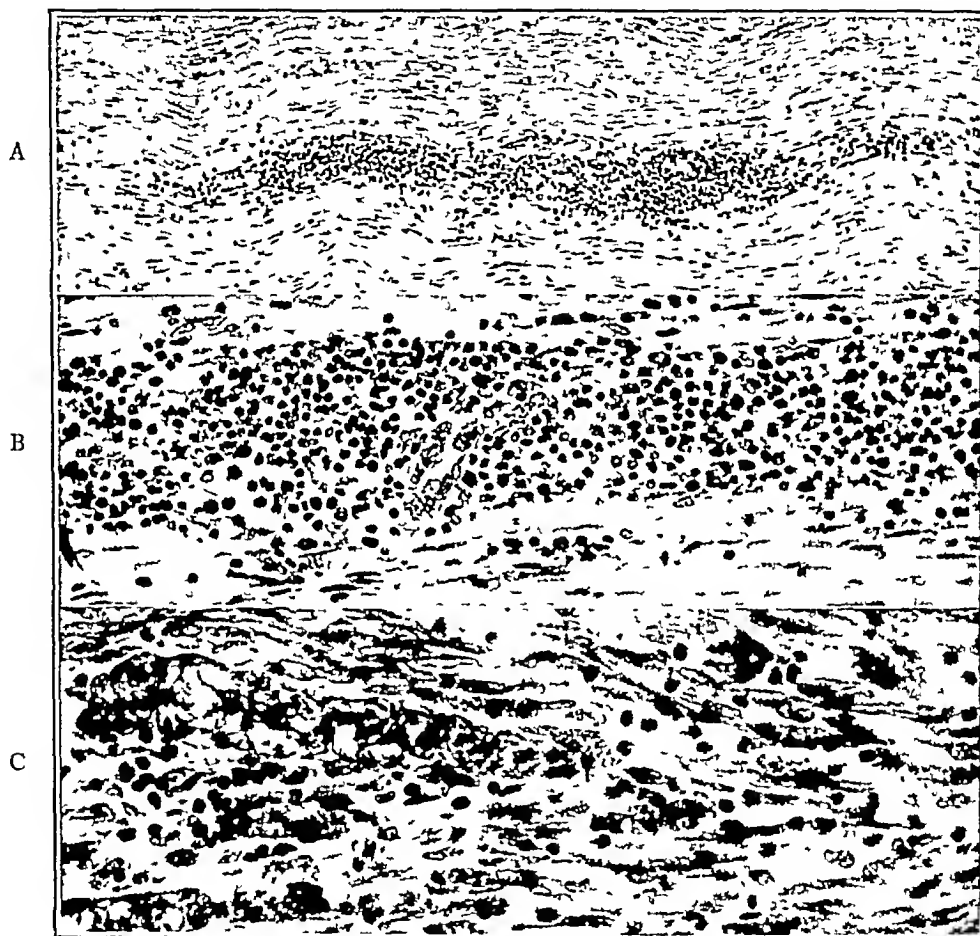

FIGURE 2 A Shows a Phloxine-Methylene Blue Stain of Peroneal Nerve, with Cellular Infiltration, and B a Higher Magnification of the Same Lesion to Demonstrate the Type of Infiltrating Cells C Shows a Sudan III Stain of the Same Nerve (Note the Swollen, Vacuolated and Fragmented Myelinated Nerve Fibers)

fluid pressure was normal, the fluid was slightly yellow, it contained 20 mononuclear cells per cubic millimeter, the sugar was 54 mg, and the protein 112 mg per 100 cc, the Wassermann test was negative. Several brief, generalized convulsions occurred on the 17th hospital day, and during some of these the radial pulse disappeared. A few minutes after a convulsion respirations suddenly ceased at a time when the pulse was quite strong. Death occurred on the 17th day in the hospital.

Autopsy External examination of the body revealed nothing of note except for slight jaundice of the scleras and skin. The heart weighed 640 gm. The left auricle was dilated to about twice its normal capacity, the endocardium varied from pale to yellowish white and was calcified in two places. Both leaflets of the mitral valve were greatly thickened, and

aortic valve 7.7 cm in circumference, the right ventricle was 0.6 cm, and the left 1.7 cm in thickness.

The spleen weighed 580 gm. The surface was smooth and purplish gray. The cut surface was firm and purplish-red, and the malpighian corpuscles were well demarcated. The pulp was firm, and very little could be removed by scraping.

The liver weighed 1680 gm. The surface was smooth and reddish brown. The cut surface was firm, and the lobules were well demarcated by pink periportal tissue. The central veins could not be seen. The gall bladder and bile ducts were normal.

There was a generalized lymph-node enlargement. The nodes in the mesentery averaged about 2.0 cm in diameter. The largest mediastinal lymph node measured 2.5 by 2 by 1 cm, and the periaortic nodes were 4 by 4 by 1 cm. One lymph node adjacent to the common bile duct measured

4 by 2 by 1 cm hnt did not obstruct the flow of bile. There were five discrete lymph nodes along the hepatic duct. The axillary and inguinal nodes averaged 1.0 by 0.4 by 0.4 cm. The cut surface of all these nodes was firm homogeneous and pinkish white.

The brain weighed 1380 gm. The leptomeninges of the brain and spinal cord were thin and transparent. There were no gross abnormalities of the brain spinal cord or peripheral nerves.

Microscopical examination disclosed that there was an infiltration of plasma cells lymphocytes a few polymorpho-

The upper and lower lobes of the right lung and the upper lobe of the left lung revealed an interstitial infiltration of a moderate number of plasma cells, some lymphocytes and immature mononuclear cells of an undetermined type. The alveoli of these lobes were free from exudate except for the presence of a few 'heart failure' cells in some alveoli. The alveoli of the left lower lobe contained numerous polymorphonuclear leukocytes, some large mononuclear cells, many of which contained phagocytosed cells, and occasional immature mononuclear cells with a basophilic cytoplasm, type of cell undetermined. The alveolar capillaries contained

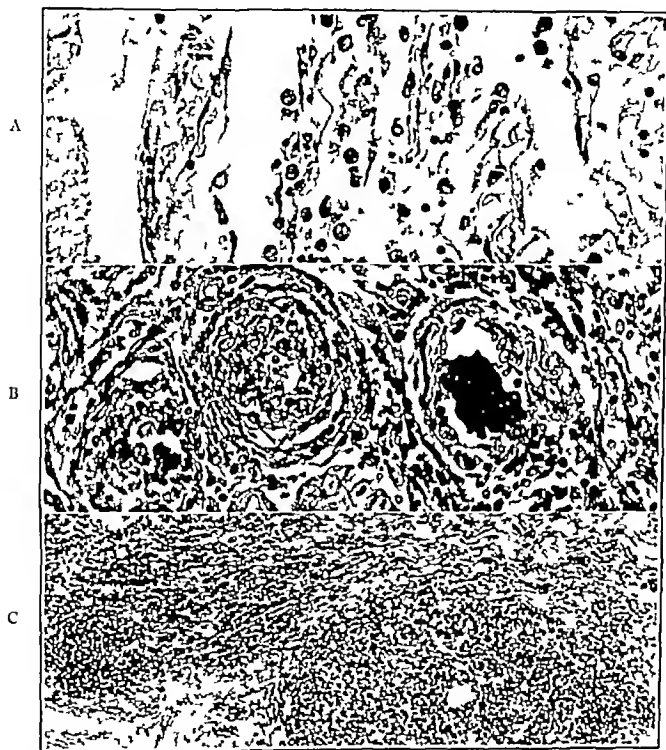

FIGURE 3 A Illustrates a Phloxine-Methylene Blue Stain of the Spinal Leptomeninges, Showing Cellular Infiltration. B a Cajal Silver Stain of a Spinal Ganglion (One Nerve Cell is Shrunken and Pyknotic and the Other Two are Disintegrated) and C a Sudan II Stain of a Spinal Ganglion to Show Cellular Infiltration and Nerve Cell Degeneration.

nuclear leukocytes and some large mononuclear cells both around and within the nerves of the epicardium. A few cells of the same types were scattered through the fat tissue. The myocardium showed a patchy interstitial infiltration of similar types of cells with more polymorphonuclear leukocytes present than in the epicardium. In addition there were occasional perivascular lesions consistent with Aschoff bodies. The endocardium contained a focal infiltration of cells of the same types seen in the myocardium and epicardium.

Both the mitral and aortic valves showed a marked increase in collagen and vascularization.

polymorphonuclear leukocytes, some plasma cells, some immature mononuclears as described above and mast cells. The bronchioles contained an exudate similar to that in the alveoli. The alveolar walls were thickened and congested, and some showed swelling of the alveolar lining cells. The arterioles revealed hyperplastic changes, and an occasional one a necrotizing process. In a large artery there were sub-endothelial lipid cells and an infiltration of plasma cells and immature mononuclear cells. Stains for bacteria showed positive diplococci in the polymorphonuclear leukocytes alveolar and bronchiolar exudates.

The submucosa of the trachea was infiltrated with plasma cells.

Some of the malpighian corpuscles of the spleen were small and inactive. Others had been replaced by plasma cells, histiocytes and occasional giant cells of the Langhans type. The endothelium of the central arterioles in such follicles was swollen. The pulp was congested and contained numerous plasma cells and polymorphonuclear leukocytes.

The ganglions and the nerves of the stomach were infiltrated with cells as described elsewhere. The muscularis showed an interstitial infiltration.

There was an interstitial infiltration of some plasma cells, lymphocytes, large mononuclear cells and a rare eosinophil

There was a focal infiltration of plasma cells, lymphocytes and a rare eosinophil in the interstitial tissue of the kidneys (Fig 1B). A stain for fat showed none to be present.

Sections from the lymph nodes from various regions showed essentially the same picture. Their structure was well preserved. The germinal centers were inconspicuous and inactive. The sinuses contained large mononuclear cells, some of which had phagocytosed red cells. In the sinuses there were also a few immature cells. The surrounding connective tissue was infiltrated with plasma cells and lymphocytes.

In sections from the bone marrow the granulocytic series were numerous, with normal maturation. An unusual number of eosinophilic myelocytes were present. Cells of the red-cell

FIGURE 4 A Demonstrates a Cresyl Violet Stain of the Lumbar Spinal Cord to Show Meningeal and Focal Infiltrations, and B a Higher Magnification Showing One of the Lesions in the Gray Matter (the Nodule Consists of Lymphocytes, Plasma and Mononuclear Cells Mixed with Microglial Cells and Astrocytes)

in the pancreas. A small ganglion disclosed lesions similar to those described elsewhere.

The liver cells in the centers of the lobules had disappeared, and in the spaces formerly occupied by them were plasma cells, polymorphonuclear leukocytes and large mononuclears, some of which contained pigment. An occasional necrotic liver cell invaded by leukocytes was present. A considerable number of bile capillaries were distended with bile. The cells showed a moderate degree of fatty and hydropic degeneration. The portal areas were infiltrated with numerous cells, polymorphonuclear leukocytes, occasional plasma cells and large mononuclear cells (Fig 1A).

series were markedly decreased in number. The megakaryocytes were not remarkable. In the sections from the vertebral and sternal marrow were several focal lesions made up of histiocytes and giant cells of the Langhans type.

There was an interstitial infiltration of plasma cells and lymphocytes in the salivary gland.

The pituitary body showed a perivascular infiltration of plasma cells, lymphocytes and large mononuclears in the posterior lobe.

Sections of the peripheral nerves, dorsal and ventral lumbar roots, spinal ganglions, spinal cord, medulla, cerebellum, mid-brain, thalamus and cerebral cortex were stained

with cresyl violet. The nerves and ganglions were also stained with ORO for fat, hematoxylin for myelin and silver for axon cylinders.

All the nerves, even the most peripheral twigs were infiltrated with large aggregates of lymphocytes and plasma cells, unidentified mononuclear cells and a few polymorphonuclear leukocytes. Histocytes were also increased in number. These cells were in the endoneurium, separating the nerve fibers and had also invaded the perineurium. The spinal sensory ganglion cells and sympathetic ganglions in the bowel and bladder were similarly affected. Most of the ganglion cells had disappeared and were replaced by clumps of satellite cells and phagocytes. Scattered nerve fibers had degenerated and round and oval shaped remnants of destroyed myelin remained. In only a few places had these myelin products been phagocytized by histocytes. The majority of myelinated fibers were intact. The spinal roots were less involved than the nerves. The spinal and cerebral meninges contained infiltrations of lymphocytes, plasma cells and mononuclear cells and similar cells extended into the posterior horn via the entering root fibers. There were several clumps of microglial cells and lymphocytes and mononuclear elements in the white matter especially around blood vessels. Some of the anterior-horn cells were swollen and had undergone chromatinolysis. A few small blood vessels in the brain and spinal cord were surrounded by lymphocytes and plasma cells (Figs. 2, 3 and 4).

Cultures of the lungs, other organs and blood were not taken. Attempts to culture the lymph nodes and the spleen on chick embryos were unsuccessful, since the material was contaminated with an organism of the *Escherichia coli* group.

The anatomic diagnoses were acute infective polyneuritis, with extensive involvement of the peripheral nerves, spinal roots and sensory and sympathetic ganglions, acute interstitial myocarditis, hepatitis and nephritis, rheumatic heart disease, healed and active, stenosis and insufficiency of the mitral and aortic valves and bronchopneumonia of the left lower lobe.

In the following case the patient recovered after a few weeks, and hence the diagnosis was not verified pathologically, but the resemblance to Case 1 was so close that the clinical details are added to emphasize the greater frequency and non-fatal character of some cases.

Case 2.* A 46-year-old man had been well until 3 weeks previously, when he became febrile and tired and voided dark brown urine. He improved after 3 or 4 days, returning to work, but malaise continued. Two weeks before admission he became anorectic and jaundice was noted, deepening during the next week, when numbness and tingling of the fingers and, soon afterward of the toes and feet set in. The paresthesia rapidly extended up the legs and were accompanied by muscular weakness of such severity that the patient could not stand or walk. There had been a 10-pound weight loss.

Notable items in the past history were rheumatic fever at the age of 17 years and the absence of exposure to a jaundiced person to metals, to transfusion or to inoculation.

Physical examination disclosed a mentally alert and co-operative patient. The skin was moderately jaundiced. There was a slight enlargement of all palpable lymph nodes. The heart was enlarged, the border of cardiac dullness extending 10 cm. to the left of the midclavicular line, the second pulmonic sound was louder than the aortic, and a Grade III rasping systolic and a low pitched rumbling diastolic murmur were heard at the apex. The liver had an increased vertical diameter the lower edge being 5 or 6 cm. below the costal margin at the midclavicular line. The spleen was not palpable. There was no facial weakness or other disturbance of the cranial nerves. The muscles of the arms and legs were partially paralyzed. The legs were more affected than the arms and the proximal muscles slightly more than the distal ones. The muscles were tender and flaccid. All tendon reflexes, including the plantar, were absent, and the abdominal reflexes were retained. Vibratory and position senses were

reduced below the knees and in the hands. Touch sensation was questionably impaired and other forms of cutaneous sensation were preserved.

The temperature was 98 F, the pulse 88, and the respirations 20. The blood pressure was 120/60.

Examination of the blood revealed a hemoglobin of 105 per cent and a white-cell count of 12,400 with 83 per cent neutrophilic leukocytes, 8 per cent lymphocytes, 8 per cent monocytes and 1 per cent eosinophils. The nonprotein nitrogen and fasting blood sugar were normal. The cerebrospinal fluid was under normal pressure and except for a total protein of 80 mg per 100 cc. was normal. Tests for porphyrins (Watson method) were negative. Heterophil-antibody agglutinations were positive in a dilution of 1:64. The hürbabin was 3.85 mg per 100 cc. and the icteric index was more than 100. The cephalin flocculation test was +++++. The total blood protein was 7.7 gm per 100 cc. with 4.1 gm of albumin and 3.6 gm of globulin. The prothrombin time was 76 per cent. The urine contained urobilinogen in dilutions of 1:128 and gave a ++ test for hile but no albumin or cells were observed in the sediment. An electrocardiogram was normal.

During the last week in the hospital the degree of motor and sensory paralysis increased even though the jaundice lessened perceptibly. The patient became unable to lift his legs from the bed or to sit up without using his arms. All forms of sensation, including pain and touch, were impaired below the knees and elbows. Pain and burning paresthesia of the feet were experienced. The total protein in the cerebrospinal fluid rose to 143 mg per 100 cc. and there were 7 lymphocytes per cubic millimeter. The treatment consisted of bed rest, an ample intake of carbohydrate, protein and vitamins and intravenous aminoacids.

Throughout the following month the jaundice gradually disappeared, and strength and sensation slowly returned to the limbs. At the end of 3 months the patient had almost completely recovered. The only residual neurologic sign was absent ankle reflexes. The liver function was much improved, the cephalin-flocculation test was + and the icteric index 10. The last spinal fluid protein during the 8th week of the illness was still 68 mg per 100 cc.

The final diagnoses were acute infective polyneuritis, acute interstitial hepatitis and rheumatic heart disease with cardiac enlargement, mitral stenosis and regurgitation compensated (Grade I).

DISCUSSION

Case 1 presented several puzzling features. With the development of "sore throat" and the abnormal lymphocytes in the circulating blood a diagnosis of acute infectious mononucleosis was entertained. However, the repeatedly negative tests for heterophil antibodies failed to substantiate this possibility. Then, when jaundice appeared and reduced liver function was demonstrated, the obvious diagnosis was acute infectious hepatitis, which would also have explained the abnormal lymphocytes in the blood smear. When, however, neurologic symptoms became manifest, the diagnosis was again unsettled. We knew of examples of both infectious mononucleosis and infectious hepatitis that were complicated by involvement of the nervous system but could not recall a case of an acute symmetrical polyneuritis associated with either of these diseases.

Post-mortem examination clarified some but not all of the peculiar clinical findings. The generalized weakness, dyspnea and dependent edema, the flatulence and abdominal distress and the albuminuria and slightly elevated nonprotein nitrogen were due to healed rheumatic heart disease and congestive heart failure. The finding of Aschoff bodies in the myocardium provided an explanation

*This patient was observed in one of the medical wards of the Boston City Hospital while the report on Case 1 was being prepared.

for the abnormalities in the electrocardiogram. The upper abdominal pain could hardly have been caused by congestion of the liver, since it occurred when the heart disease was quite well compensated, a more likely possibility was enlargement of the abdominal lymph nodes or of the liver occurring in the terminal illness. The jaundice and impaired liver function were ascribed to the acute interstitial hepatitis or to a combination of hepatitis and central hemorrhagic necrosis. The atypical lymphocytes in the peripheral blood and the leukocytosis were probably part of an infectious disease that mobilized lymphocytes and other mononuclear cells for the extensive cellular infiltrations found in all the nerves and visceral organs. The paresthesias and sensory impairment and the ascending paralysis and reflex loss were manifestations of the acute polyneuritis. The cellular infiltrates in the spinal and cerebral leptomeninges and in the roots were the source of the cells in the cerebrospinal fluid. The convulsions may have been due to heart block (Adams-Stokes syndrome) or the leptomeningitis, and the foci of cellular infiltration in the brain and mental confusion may have had a similar basis. Death was due to the polyneuritis, which finally produced respiratory paralysis, the pneumonia being a contributing factor.

The pathological findings in this case were in general similar to those of the class of diseases called acute infective polyneuritis, the characteristics of which are widespread but uneven lymphocytic, plasma-cell and mononuclear infiltrations of the peripheral nerves, somatic and autonomic spinal ganglions and spinal nerve roots*, irregular degeneration of myelinated peripheral-nerve fibers, varying degrees of change in the nerve cells of the spinal and autonomic ganglions, and swelling and central chromatolysis (axonal reaction) of the motor cells in the anterior and lateral horns of gray matter in the spinal cord. However, Case 1 differed in that the destruction of ganglion cells was much more extensive and the leptomeninges were infiltrated with lymphocytes, plasma and mononuclear cells—a reaction that occurs infrequently in acute infective polyneuritis. Despite these differences, some of which may be only quantitative, it seems to us that the most acceptable classification is in the group of diseases called acute infective polyneuritis. Whether the latter is a single pathologic entity or a pathologic reaction occurring in several different diseases has not been determined.

The histologic changes in the lymph nodes were not those described by Gall and Stout² in infectious mononucleosis. According to these authors, the most striking changes are seen in the germinal follicles and the extrafollicular lymphoid tissue.

*Without cellular infiltrations, assuming of course that sufficient sections of the peripheral nerves, ganglions and roots are available for study, the pathological diagnosis must remain in doubt. It should be remembered that, on clinical grounds alone, polyneuritis due to toxic and metabolic disorders may closely resemble the acute infective variety.

The germinal centers are hyperplastic and contain immature cells, presumably stem cells, and histiocytes, many of which contain phagocytosed material. Mitotic figures are numerous. The extrafollicular lymphoid tissue, both cortical and medullary, contains large cells with basophilic cytoplasm. These cells they believe to be identical with the large mononuclear cells in the circulating blood, which are considered characteristic of infectious mononucleosis. Sections of the lymph nodes in Case 1 showed small, inactive follicles and none of the cells in the lymphoid tissue seen in infectious mononucleosis.

Nor were the lesions in the liver similar to those observed in the acute form of epidemic hepatitis described by Wood³ and by Lucké and Mallory.⁴ In acute epidemic hepatitis the destructive process is extensive, and usually all the liver cells are affected, although at times a narrow zone of liver cells persists at the periphery of the lobule. Furthermore, there are a proliferation of small bile ducts and an extensive cellular infiltration of the portal areas with large mononuclear cells, lymphocytes and plasma cells and some polymorphonuclear leukocytes and eosinophils. In Case 1 the liver showed a late stage of central necrosis, with the greater portion of each lobule unaffected, and there was no proliferation of the bile ducts. The cellular infiltrates in the portal areas were similar to those in acute epidemic hepatitis, but these are not characteristic of any one disease, such cellular infiltrations being seen in varied types of infection. The lack of hyperplasia and necrosis in the lymph nodes and spleen must be regarded as further evidence against epidemic hepatitis.

In short, then, autopsy in Case 1 showed lesions in the liver compatible with those in cardiac failure and an extensive interstitial cellular infiltration in practically every organ examined. The abnormal cells found in the blood stream were similar to the unidentified mononuclear cells seen in the visceral infiltrations. Their nature and histogenesis are obscure.

The association of visceral lesions in fatal cases of acute infective polyneuritis has been recognized by other workers. Lhermitte,⁵ in 1929, and Lelong and Bernard,⁶ in 1935, reported clinical cases in which acute polyneuritis was combined with icterus or subicterus. Bradford et al.,⁷ McIntyre⁸ and more recently Sabin and Aring⁹ presented cases in which acute infective polyneuritis was accompanied by visceral lesions. These lesions consisted of infiltrations of lymphocytes, plasma cells and mononuclear cells in the liver, adrenal glands, kidneys and heart. Ours is the first case, however, in which there was both clinical and pathological evidence of visceral lesions.

Such a case raises interesting questions regarding the relation between acute infectious mononucleosis, acute infective polyneuritis and acute hepatitis.

Until the etiology of one or all of these diseases has been determined this matter cannot be definitely settled. It is our impression, however, that there are important clinical and pathological differences.

Unfortunately, no systematic attempt was made to culture a bacterium or virus in Case I. The pathological findings support the proposition submitted by Sabin and Aring that acute infective polyneuritis is a widespread systemic disease caused by a virus or bacterial toxin that involves the peripheral nervous system predominantly but may produce extensive visceral lesions of such severity as to become clinically manifest in exceptional cases.

SUMMARY

An unusual case of acute infective polyneuritis with jaundice and atypical lymphocytes in the peripheral blood and pleocytosis in the cerebrospinal fluid is reported. The pathological changes consisted in lymphocytic, plasma and mononuclear-cell infiltrations of the peripheral nerves, ganglia and leptomeninges, widespread degeneration of the

larger nerve fibers in the peripheral nerves and spinal roots, destruction of the nerve cells in the spinal and sympathetic ganglia, and interstitial infiltration of the liver, kidneys, heart and other viscera with cells similar to those in the nerves.

A similar case in which the patient recovered and the diagnosis was therefore not verified pathologically, is presented.

EMPHYSEMATOUS GASTRITIS*

CLAUDE E. WELCH, M.D.,† AND CHESTER M. JONES, M.D.‡

BOSTON

THE term "emphysematous gastritis" has been employed to designate an infection characterized by the presence of numerous small gas bubbles throughout the wall of the stomach. The lesion is closely allied to phlegmonous gastritis and to cystic pneumatosis, but has certain distinguishing features. Because this disease is so rare, an additional case report is presented below.

In the first case of this type, described by Fraenkel¹ in 1889, the patient died after several attacks of severe abdominal pain, bloody vomitus and diarrhea. Autopsy disclosed that the wall of the stomach was filled with masses of bacteria and small gas bubbles. Fraenkel named the disease "emphysematous gastritis"—a descriptive term that is not entirely satisfactory, since although it describes the presence of gas, it does not emphasize the element of infection.

A somewhat similar case was reported by Morton and Stabins² in 1928. This patient also died, and *Bacillus welchii* (*Clostridium perfringens*) was identified as the causative agent.

In the most recent case, observed by Weens,³ the patient swallowed several ounces of hydrochloric acid. Severe abdominal pain was followed by bloody vomitus. X-ray films of the stomach showed

characteristic gas bubbles throughout the wall. The emphysema gradually diminished, but extensive scar formation followed. The patient finally died of sepsis following a gastrostomy. At autopsy a subdiaphragmatic abscess and multiple liver abscesses containing colon bacilli were found. Weens has summarized the literature, and has found no other cases of true emphysematous gastritis, although emphysematous infections of other viscera, such as the gall bladder, urinary bladder and uterus, have been recorded.

DIAGNOSIS

The essential diagnostic features are severe abdominal pain, nausea and vomiting of blood, prostration, fever, leukocytosis and a typical x-ray picture. The course is usually progressively downhill with death from sepsis.

The disease must be differentiated from acute phlegmonous gastritis and cystic pneumatosis. Phlegmonous gastritis⁴ is frequently ushered in by an alcoholic bout, or follows a chemical poison, such as hydrochloric acid, or trauma, such as esophagoscopy. The clinical course is much the same, but x-ray films do not reveal any intramural gas. The mortality is recorded as about 50 per cent.

Cystic pneumatosis is characterized by the presence of localized masses of gas-filled cysts in the wall of a viscus. It is uncommon in the stomach, with 175 cases of involvement of the small

†Associate in surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital.

‡Clinical professor of medicine, Harvard Medical School; physician-in-charge, Massachusetts General Hospital.

bowel have been collected by Jackson⁵ The accumulations of gas are asymptomatic and are usually found to be incidental to other lesions at laparotomy If left alone, they tend to disappear spontaneously Baumann-Schenker⁶ has reported the only case of cystic pneumatosis of the stomach that has been recognized by x-ray study before operation

Robbins⁷ believes, from an x-ray point of view, that all cases in which intramural gas bubbles are demonstrated are variants of cystic pneumatosis It is our opinion, however, that cystic pneumatosis has only one feature in which it resembles emphysematous gastritis the presence of gas But in this respect also there is a variation, for the gas in the cystic pneumatosis is usually found in grape-like clusters of cysts, whereas in emphysematous gastritis, it is scattered throughout the walls of the stomach Emphysematous gastritis is much more closely related to and should be considered a special variant of phlegmonous gastritis

CASE REPORT

J. C. (M.G.H. 529108), a 15-year-old girl was admitted to the hospital at 8 a.m. on April 28, 1946, complaining of severe abdominal pain She had been entirely well until 36 hours before entry Soon after eating dinner, which included fresh salmon but nothing else unusual, she experienced epigastric

FIGURE 1 Scout Film of the Left Upper Quadrant of the Abdomen on the Sixth Day of the Disease

Multiple small gas bubbles are visible throughout the fundus of the stomach There is no free gas in the peritoneal cavity Fluid is present in the left pleural cavity

distress The remainder of the family, who had had the same meal, had no unusual symptoms During the night, epigastric cramps developed and were followed by nausea and vomiting Shortly after the first attack of vomiting, the bowels began to move and there were five loose movements in the following 12 hours After several episodes the vomiting ceased but the nausea continued The abdominal pain continued to increase in severity It remained in the epigastrium, finally radiating directly behind the sternum It became steady and then more intense A physician was called 18 hours before entry Paregoric was prescribed Four hours later the patient was seen by a surgical consultant, who found that the abdomen was soft throughout and not distended Peristalsis was normal It was believed that she had an acute gastroenteritis that would respond to rest

Four hours before entry, the pain became much more severe and was somewhat relieved by sitting up in a chair At that time, 8 mg. of morphine given intramuscularly had no effect upon the pain, the abdomen had become silent and more distended The patient looked definitely sicker than she had before and felt very ill

Physical examination showed a rather frail, extremely pale girl who was obviously very sick The skin was cool and

FIGURE 2 Roentgenogram on the Tenth Day, Showing Multiple Gas Bubbles in the Wall of the Body of the Stomach No areas of mucosal ulceration could be demonstrated

moist The heart and lungs were normal The abdomen was markedly distended, rigid, tender throughout and silent Rectal examination was negative

The temperature was 99.5°F by rectum, the pulse 125, and the respirations 25 The blood pressure was 72/26

Examination of the blood disclosed a white-cell count of 39,500, with 96 per cent neutrophils, 2 per cent lymphocytes and 2 per cent monocytes A urine specimen could not be obtained

A nasal tube was passed immediately, and to our great amazement a total of 2000 cc. of coffee-grounds liquid was obtained from the stomach This produced some improvement in the general condition The abdomen became softer and less tender The diagnosis of acute hemorrhagic gastroenteritis seemed the most tenable The patient was immediately given intravenous injections of dextrose in physiologic saline solution, with resulting improvement of the systolic blood pressure, which rose to approximately 100 Eight hours later, she was very toxic and disoriented Climbing out of bed, she pulled out the intravenous needle A few minutes thereafter she developed a severe state of shock, and when seen at that time, it appeared that death was imminent While blood transfusions were being prepared, 250 cc. of plasma was rapidly given This was followed by 850 cc. of whole blood At that time, the temperature was 104°F by

rectum the pulse 160 and the respirations 25. During the first 24 hours in the hospital the patient received a total of 3800 cc. of physiologic saline solution plasma and blood intravenously and maintained a urinary output of 600 cc.

On the following morning she was slightly improved. She was still very toxic and dehydrated with a silent distended abdomen that was slightly tender throughout. The drainage from the intubing Levin tube was still profuse and coffee ground in nature. She then began to run a septic type of temperature with a rise to 102 F. every evening and a pulse ranging up to 120. Two days after entry the gastric drainage had cleared considerably and for the first time showed a gross blood. A hemoglobin (photo) of the gastric content that were aspirated during that period was 4.6 gm. It was estimated that the amount of blood lost from hemorrhage was therefore at least 1000 cc. Three days after entry it was possible to start feeding by mouth. The abdomen was still somewhat distended but peristalsis had returned to normal. Examination of the chest at that time showed no evidence of fluid at the left base and some edema of the face had developed. Fluid in the chest gradually increased in amount. On the 7th day a chest tap was done. A total of 360 cc. of straw-colored slightly cloudy fluid was withdrawn after which 25 000 units of penicillin was inserted. The chest fluid showed no growth on culture.

At the time of entry an x-ray film had been taken of the abdomen. This was not remarkable except for the presence of several gas filled loops of small bowel. Six days after entry, repeat plates were made. At that time a most remarkable picture was observed. The stomach was seen to be dilated, containing a large quantity of gas. Surrounding the entire fundus of the stomach and extending well down on the antrum were numerous small gas bubbles which were found on all walls of the stomach but no evidence of free gas in the peritoneal cavity could be found (Fig. 1). Fluid filled the lower two thirds of the left pleural cavity. The x-ray film superficially suggested a stomach full of masses of food but we were certain that the stomach was empty of solids and fluid.

With the presence of an increasing amount of fluid in the left side of the chest and disappearance of the edema elsewhere it was believed that a subdiaphragmatic abscess was developing. The penicillin dosage was increased. Ten days after entry barium was given by mouth. By a barium meal the air bubbles throughout the fundus were shown to be within the gastric wall (Fig. 2). No areas of ulceration could be demonstrated in the stomach and the duodenal cap and loop were normal. There was no evidence of subdiaphragmatic inflammatory change or massive pleural effusion. There was no movement of the left leaf of the diaphragm.

Within the following week the temperature gradually declined and the patient finally became afebrile about 2½ weeks after entry. Penicillin was discontinued 3 days later. Three weeks after entry x-ray examination showed the swallowing function to be normal. No disease was noted in the esophagus stomach or duodenum. The fundal portion of the stomach was displaced downward from the left leaf of the diaphragm probably owing to inflammatory changes taking place in that region. The left leaf of the diaphragm showed marked limitation of motion. The fluid in the chest had disappeared. Meanwhile, the white-cell count had gradually declined to normal, and the hemoglobin was maintained at 12 gm.

Specific therapy consisted chiefly of penicillin of which 192,000 units was given intramuscularly daily for the first 5 days. This dosage was then increased so that approximately 300,000 units was administered daily. Sulfadiazine was given intravenously at entry. A maximum blood level of 4.2 mg. per 100 cc. was obtained. The sulfadiazine was discontinued after the initial dose because of the low urinary output and fear of renal complications. The patient also received large doses of adrenocortical extract during the period in which she was in shock. Large doses of vitamins K, C and B were given intravenously. She received a total of five blood transfusions. Unfortunately no Amigen was available at the time but the serum protein was maintained over a level of 5.5 gm. per 100 cc. during the hospital stay.

Culture of the gastric contents shortly after entry showed abundant *Escherichia coli*, a moderate number of non-hemolytic streptococci and a few colonies of *Staphylococcus aureus*. Stool cultures on the first available specimen showed no pathogenic organisms.

During the illness the weight had dropped from 85 to 67 pounds. A month after discharge the patient was entirely asymptomatic and had gained 8 pounds. Repeat x-ray films at that time showed no disease in the chest or stomach. A year later the patient reported that she was in perfect health and had had no further gastric symptoms.

DISCUSSION

The cause of the disease in this patient is not clear. It is probable that she first had an acute gastroenteritis, accompanied by vomiting, which produced rupture of the gastric mucosa. This was followed by profuse bleeding and gastric dilatation and then by an invasive infection of the wall of the stomach with nonspecific organisms. It is possible that gas within the lumen of the stomach was actually forced into the stomach wall as well as through mucosal rents, although the wide distribution suggested the formation of gas bubbles by the invasive bacteria.

Although a mixture of *Esch. coli*, nonhemolytic streptococci and *Staph. aureus* was found in the gastric contents, the exact organisms that invaded the gastric wall were not known. Occasionally, mixed infections of *Esch. coli* and nonhemolytic streptococci will produce gas, thus, gas is observed in infections of the leg, or in subdiaphragmatic abscesses from which these organisms can be grown. It can therefore probably be assumed that this mixed infection was the source of the gas.

The extreme prostration was due primarily to blood loss and secondarily to infection. The blood loss, judging from the hemoglobin level of the gastric contents, was at least 1000 cc. After this blood had been replaced, the signs of sepsis became more apparent. The subdiaphragmatic inflammation gradually subsided without the formation of a definite abscess.

Recovery from infection, we believe, was due chiefly to the rather large doses of penicillin employed. The early administration probably maintained the sterility of the subdiaphragmatic and intrapleural fluid collection. Similarly, control of the intragastric infection prevented the development of late scar formation and gastric deformity.

SUMMARY

To 3 cases of emphysematous gastritis collected from the literature a fourth is added. The other 3 patients died. The patient in the case presented above, after penicillin therapy, recovered without complications.

WHAT INDUSTRY THINKS ABOUT THE MASSACHUSETTS MEDICAL SOCIETY'S PROGRAM OF MEDICAL CARE FOR THE PEOPLE OF MASSACHUSETTS*

JARVIS HUNT†

NORTH ATTLEBORO, MASSACHUSETTS

GRANTING that it is necessary to provide more adequate medical care for our citizens, the question arises, How shall this care be distributed? How shall it be administered, and how shall it be financed? Naturally, the further question also immediately arises, What part should the United States Government have in this program? At the present time several bills regarding medical care are pending before Congress. The most important of them are the Wagner-Murray-Dingell Bill (S 1606), the Maternity and Child Welfare Act of 1945 (S 1318) and the Taft Bill (S 545).

The basic principles of medical care as presented by the Society list two main questions. The first is the provision of adequate medical care for those who cannot afford it. The second is the furnishing of that care for those who can afford it. Very properly, I think, the first principle listed is that medical care by voluntary prepayment plans or by direct payment is the responsibility of the local or state government. Part of the burden of this responsibility may be assumed by charitable agencies, such as the various community funds, and part of it by federal grants to state programs, to be administered by state boards of health. This, I think, is one of the fundamental principles of any medical-care program—that it be administered by the government that is closest to the people—that is, by the state or local government. Because the federal Government has at the present time taken over so many of the fields of taxation it seems essential that the financial aid should come from the federal Government. Its administration, however, should be handled on the local level.

The second principle is correctly stated as medical care of those who are able to purchase it by voluntary prepayment plans or by direct payment, which is the responsibility of the individual. In this field government participation should be purely supplementary and educational, and probably any government assistance in a financial way should be along those lines.

The basic principles also state that the eligibility for receiving benefits aided by federal grants should be determined by the individual states, that in any event the patient should have the free choice of his physician, group of physicians, clinic or hospital from among those participating in any plan, government or voluntary, and that on the

other hand the physician, group of physicians, clinic or hospital should have the right to refuse or accept the patient and the individual physician should be free to elect or reject without prejudice his individual participation in any medical-care plan, furthermore, physicians, hospitals and nurses should receive adequate remuneration for their services. These principles are essential if citizens are to have the freedom of choice and the recognition of individual rights that are an inherent part of the system of free enterprise. Industry is strongly opposed to any form of socialized medicine, which is merely one step farther toward actual socialism, and the Wagner-Murray-Dingell Bill, especially Title 2 of this act, is no more or less than compulsory health insurance. Industry is very wary of any compulsory government programs, having been burnt by a good many during the last few years.

The Society's principles are carried out in great part by the prepayment hospital plan, the Blue Cross, which is said to act for about 50 per cent of hospital admissions and after ten years of experience has come to be an accepted and important part of the medical program of the Commonwealth. The Blue Shield, which covers surgical and obstetric care rendered in the hospital for approximately 600,000 persons in the Commonwealth and which soon will cover all medical hospital care and surgical and medical services rendered outside the hospital, very ably complements the Blue Cross.

The third operating program of medical care, that of the United States Veterans Administration, covers approximately 600,000 Massachusetts veterans through all types of medical care. Thus, a large proportion of the five million people in the Commonwealth participate in one or more of these three plans.

From the point of view of industry, the Workmen's Compensation Act provides not only hospital, surgical and medical care for all persons injured in industry or in any commercial enterprise or those who are suffering from an occupational disease incurred in the course of their employment but also certain cash benefits for specific injuries and a weekly payment with a maximum of \$25 in addition to \$2.50 for each dependent during total incapacity and additional weekly payments during partial incapacity. This program covers approximately one fourth of the population and cost industry in 1946 about thirty million dollars. The gap in medical care for persons engaged in industry concerns those who are unable to work because of

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 20, 1947.

†General counsel, Associated Industries of Massachusetts.

sickness and accidents occurring outside the course of the worker's employment. Through the assistance of the Blue Cross, the Blue Shield and the Veterans Administration, as well as by voluntary sickness and accident plans set up by various industries, this gap is rapidly closing. In 1944 the Advisory Council of the Employment Security Division conducted a survey under the authority of the General Court and found that in establishments employing 20 or more persons, 65.9 per cent were covered by some form of nonoccupational sickness or accident protection.

In 1946 a further investigation by the same agency showed that in establishments employing 20 or more persons, such coverage had increased to 71 per cent, and establishments of less than 20 employees, then surveyed for the first time, disclosed that nearly 64 per cent of the workers had some degree of protection against wage losses due to illness. Thus, this gap is rapidly being closed through entirely voluntary plans.

The demand has arisen in the same quarters as the demand for socialized medicine that a cash sickness-benefit plan be made compulsory for industry. Rhode Island now has such a plan based on the employment security or state fund system. California has a plan financed through a state fund, to which contributions are made as set by law or through private plans under state supervision. New Jersey is considering a proposal, which to date has not become law, for a cash sickness-benefit plan for industry, to be financed by private operation under state supervision. After a careful study of these systems, the Advisory Council recommended that if such a system were instituted it be a privately operated plan under state supervision with the establishment of minimum standards that would preserve the present plans in operation throughout the state. This, I think, is absolutely essential if such a plan is to be put into effect. Industry, however, is not yet ready to accept a compulsory cash sickness-benefit plan. The Ad-

visory Council in its first report to the General Court in 1945 stated as follows:

the role of government should be one of added impetus to the establishment and expansion of private plans rather than in direct participation. The remarkable growth of group insurance, Blue Cross hospitalization and prepaid medical care, in addition to the long-established individual health and accident insurance policies, is evidence that in Massachusetts private enterprise is meeting the problem and will continue to assume its responsibility if permitted to do so.

This, I believe, is still the point of view of industry, and I think that it coincides with the basic principles expressed by the Massachusetts Medical Society.

In conclusion, the two principles clearly set forth, which must govern all attempts to provide further medical care for the people of Massachusetts, are that the local or state government should assume the responsibility of providing adequate medical care for those unable to obtain it (a great part of this burden should be furnished by federal grants, but the administration should be purely on the state level) and that medical care for those who are able to purchase it by direct payment, voluntary prepayment plans or payroll deductions is the responsibility of the individual. This may be met through collective-bargaining agreements with his employer if he is employed, through voluntary agreements entered into between employer and employee, through private insurance sickness and accident coverage, through the Blue Cross and the Blue Shield and through benefits granted because of the applicant's status as a veteran. Before any compulsory plans are instituted along these lines, the voluntary plans listed above should have a chance to expand and to meet the responsibility. Furthermore, any plan, whether governmental or voluntary, must contain certain safeguards so that there will be absolute freedom of choice between patient, physician and hospital, and adequate remuneration for those whose services are given under such plans.

Correction On Page 772, in the fourth line of the last paragraph of the summary of the paper "Syphilitic Primary Atrophy" by Drs. Levin, Trevett and Greenblatt, which appeared in the November 20 issue of the *Journal*, "artificial fever" should be changed to read "fever therapy."

MEDICAL PROGRESS

THE NASAL CARRIER OF BETA-HEMOLYTIC STREPTOCOCCI*

HENRY M. LEMON, M D †

BOSTON

IN spite of the large number of accumulated data concerning the beta-hemolytic streptococcus and its effect on the human host, we are still largely unable to control its endemic reservoir and potential epidemic spread. As a result of the tragic mortality following the influenza pandemic of 1918, intensive efforts were carried out during World War II, first in Great Britain and later in this country, to devise means of curbing the spread of hemolytic streptococci and other respiratory infections, particularly among military recruits. These studies approached the problem from many angles, including chemotherapeutic,^{1, 2} immunologic³ and environmental means of control.⁴ In spite of accurate methods of typing hemolytic streptococci,⁵ the brilliant development of a new and potent therapeutic agent such as penicillin and the advances made in the understanding of the importance of dust and air in the transport of respiratory disease,⁶⁻¹¹ no single widely applicable and effective control method was devised on either side of the Atlantic to prevent the spread of epidemic streptococcal pharyngitis and tonsillitis and their unfortunate sequelae.¹²⁻¹⁴

With this recent experience in mind, it seems that the classic public-health measures of detection and isolation or treatment of the source of epidemic infection may in the future have to be invoked more often in training camps, schools and institutionalized populations when streptococcal infection approaches dangerous levels. It is well known that the rate of streptococcal pharyngeal carriers may rise from the normal 5 to 10 per cent to a level of 50 to 60 per cent during the development of an epidemic, and until recently there was no unanimity of opinion concerning the relation of a rising carrier rate to the pathogenesis of an epidemic, frequently, clinical streptococcal disease did not parallel the carrier rate,^{15, 16} nor was there always a rise in the pharyngeal carrier rate to serve as a sign of an approaching epidemic.¹⁷ Since mass sulfadiazine prophylaxis failed, owing to the appearance of sulfonamide-resistant strains,^{18, 19} control of all the carriers has not been feasible by any method devised to date.

Hamburger and his associates²⁰ have recently proved the existence of the "dangerous" nasal car-

rier of beta-hemolytic streptococci, who disseminates at least one hundred times the numbers of organisms from his respiratory tract as patients or carriers with pharyngeal implantation only. The possibility of identifying and controlling the relatively few such carriers offers a new method of preventing streptococcal epidemics and solves many discrepancies in the epidemiologic pattern of streptococcal disease. It is the purpose of this paper to assess the evidence that the nasal carrier transmits the bulk of streptococcal infections of the respiratory tract and to review all the known factors pertaining to this condition.

METHODS USED

Recognition of the importance of nasal carriers occurred more or less as a by-product of quantitative studies of environmental contamination by the Commission on Air Borne Infection under the direction of Dr O H Robertson. In these studies extensive use was made of the conveniently identified and typed hemolytic streptococcus as an indicator organism of respiratory contagion in Army hospital wards and barracks, in the course of studies on the control of air-borne and dust-borne contagion. A number of methods were employed in these studies, many of which, although simple, reflect the efforts made to quantitate the amount of environmental contamination by patients and carriers.

The daily streptococcal output of ward patients was estimated, sterile cloth patches 12.7 by 12.7 cm being stapled overnight to the bottom sheet of the patient's bed. These were subsequently subcultured by rinsing in broth and plating aliquots, from which counts could be made.²⁰ Previous studies had demonstrated that the bottom sheet showed the highest degree of streptococcal contamination of any item of the bedding.²¹

The potential nasal streptococcal output of patients and carriers was estimated by means of the standard nose-blow test, in which, after sterilization of the hands, the nose was blown three times into a sterile handkerchief, 12.7 by 12.7 cm in diameter, which was subsequently subcultured as described above.²²

The number of streptococci residing on the hands was estimated both before sterilization and after the nose-blow test, by washing of the hands for a constant interval in a standard amount of broth, from which cultures were obtained.²²

*Presented at a symposium in honor of Lady Florey at the Evans Memorial, Massachusetts Memorial Hospitals, on April 25, 1947.

†Instructor in medicine, Boston University School of Medicine, resident physician, Evans Memorial, Massachusetts Memorial Hospitals, formerly, member, Commission on Air-Borne Infections, Army Epidemiological Board, Preventive Medicine Division, Office of the Surgeon General, United States Army.

Cultures were made of clothing, bedding and floor dust, the suction device described by Lemon²² being used. The entire exposed upper surface of the blankets as made up on the bed was "vacuumized" for a constant interval, and subcultures were made of the dirt trapped in the scrubbing chamber of the device. The outer surfaces of blouses, shirts, trousers and coats were similarly cultured, and measured areas of floor surface underneath or around carriers' beds could be sampled with the same device.

Air cultures utilizing both settling plates and the suction device previously described, as adapted for collection of air-borne bacteria, were made.²³ The suction device has a known efficiency for collection of air-suspended bacteria and virus close to 90 per cent and can sample fairly large volumes of air, from 10 to 30 cubic feet. Pour plates made from the scrubbing fluid in the sampler in suitable dilution can be studied for both total bacteria and air-borne hemolytic streptococci.

Cultures of the pharynx bilaterally in the region between the anterior and posterior tonsillar pillars were made at daily, weekly or monthly intervals as indicated. At the same time nasal cultures were obtained by the use of slightly thinner swabs rubbed over the mucosa of the anterior nares to a depth of not more than 2.5 to 3.0 cm.

All streptococcal cultures from the environment were poured in duplicate blood-agar gentian violet (in a 1,500,000 to 1,750,000 dilution) plates for counting and subsequent grouping and typing by the methods of Swift, Wilson and Lancefield.²⁴ Nose and throat cultures on plain blood agar were carefully described, and the amounts of streptococcal growth roughly estimated, prior to grouping and typing.

A limited number of carriers and healthy controls were studied for anti-streptolysin "O" titer variations, the method as modified by Rantz and Randall²⁵ being utilized.

The investigations were carried out over a period of four years (1942-1946), chiefly at Chanute Field, Illinois, Camp Carson, Colorado, Fort Lewis, Washington, and the University of Chicago School of Medicine. The co-operation of the United States Army Medical Department facilities at these posts was of great help, and the work was part of an extensive program of research administered by the Army Epidemiological Board, Preventive Medicine Division, Office of the Surgeon General.

EPIDEMIOLOGY AND CHARACTERISTICS OF THE NASAL CARRIER

Early in the course of these investigations certain basic facts became evident that later led to the nasal carrier studies. Parallel studies in hospital wards and Army barracks early in the war indicated that the rate of bacteriologic and clinical cross infection with a given type of streptococcus could usually be correlated with the predominance of this type

in the air or dust from floor and bedclothes.^{26, 27} Furthermore, analysis of the rate of air and dust contamination in different portions of a hospital ward or barracks squad room revealed definite foci from which the predominant streptococcal type originated. These marked variations in the degree and type of environmental contamination, however, could not always be related to the numbers of streptococci in the pharynx and saliva of the personnel present. Some patients with clinical pharyngitis and strongly positive throat cultures were obviously rapidly seeding their environment with streptococci, whereas many others equally sick distributed very few streptococci to their bedding, clothing or surroundings. The bedding of ambulatory pharyngeal carriers in the barracks was frequently no more highly contaminated by streptococci than that from beds of noncarriers, and in many cases there was no similarity of types, indicating that these beds had been seeded from some other source.

Eventually, a patient with clinical sinus disease was observed by Hamburger to be a most profuse disperser of streptococci, and routine nasal cultures were then instituted. These soon disclosed that almost all cases or carriers of streptococci with strongly positive nose cultures could be classified as "dangerous" in that they were seeding their environment with tremendous numbers of micro-organisms each day, as measured by any one of the several tests employed. Carriers or patients in whom the nasal cultures were weakly positive usually showed less ability to disseminate streptococci, although they often exceeded the simple pharyngeal carriers in this respect.²⁸

Since the phenomenon of dosage is of such importance in the determination of experimental infection, and since the degree of dust and air contamination must reflect the quantitative fluctuations in the sum total of streptococcal excretion by carriers and cases, it is of interest to review the differences in the numbers of hemolytic streptococci dispersed by the nasal carrier in contrast to the simple pharyngeal carrier.

Nasal carriers who were "strongly positive" were found to be capable of blowing out an average of 11,000,000 streptococci by the nose-blow test. At times as many as 1,000,000,000 organisms were expelled, and it should be emphasized that some of these patients showed minimal evidence of coryza or rhinitis. Very few if any streptococci were ever found in the nose blows of pharyngeal carriers with negative nose cultures, and weakly positive nasal carriers gave intermediate results. During induced sneezing and coughing, nasal carriers were found to excrete a significantly larger number of streptococci than the pharyngeal carriers, although no significant differences were found in the salivary content of these bacteria.²⁹

The hand washes of 74 pharyngeal patient carriers yielded an average of only 4700 streptococci per test,

whereas 106 nasal patient carriers yielded an average of 790,000 organisms. As might have been expected, sterilization of the hands of these nasal carriers by washing in soap and water followed by a rinse in 70 per cent alcohol was considerably more difficult than that of the pharyngeal carriers. The hands of

figures, no significant differences were observed between cases with and without a scarlatiniform rash.²⁰

Somewhat less marked differences in the blanket content of streptococci were noted in the barracks surveys of beds of ambulatory nose and throat carriers. Both strongly and weakly positive nasal carriers were included in the statistics, and the latter were shown to cause much less contamination of the bedding.²¹ Also, no doubt many beds showed evidences of the prolonged survival of streptococci in blankets belonging to men who had once been both pharyngeal and nasal carriers but in whom the nose culture had cleared by the time of the survey. Streptococci have been shown to survive in bedding for periods as long as 5 months.²⁷ In the barracks,

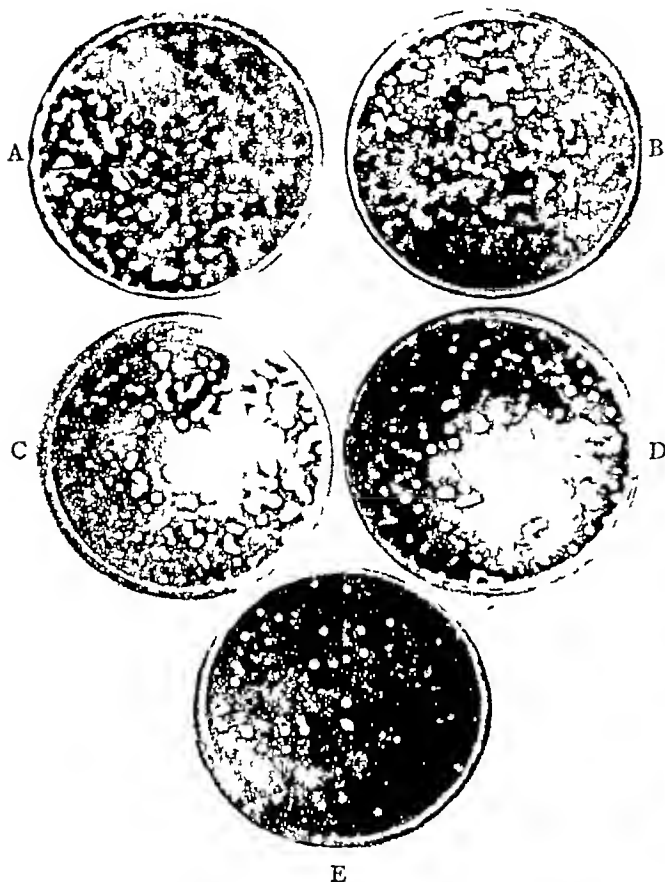

FIGURE 1 *Environmental Cultures, Using a Bubbler-Suction Sampler, from the Vicinity of an Asymptomatic Ambulatory Nasal Carrier (Nose and Throat Cultures Strongly Positive)*

A demonstrates culture of blankets on bed (75,800 streptococci), B culture of comforter (62,100 streptococci), C culture of blouse (20,200 streptococci), D culture of shirt (17,800 streptococci), and E culture of floor dust immediately surrounding and beneath bed (6700 streptococci). The figures represent only a small percentage of the total organisms present, successive samplings yield almost as many streptococci as initial tests. Plates usually represented 1/100 of the total culture.

nasal carriers were resoiled back to their original state by a few nose blows into a sterile handkerchief. Forty per cent of the pharyngeal carriers were noted to have negative hand cultures.²²

The accumulation of streptococci on the cloth patches exposed overnight on the beds of hospitalized patients occurred at a rate about one hundred times as fast in the nasal patient carriers as in the pharyngeal patient carriers. Patients with negative nose cultures usually yielded only 600 to 900 organisms by the patch test, whereas an average of 50,000–60,000 streptococci were recovered from tests on patients with strongly positive nasal cul-

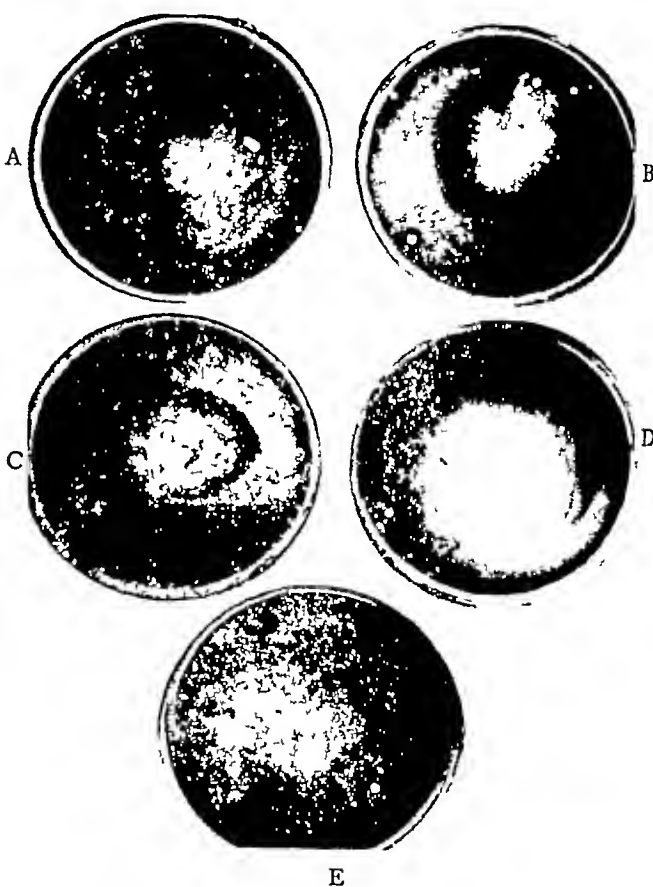

FIGURE 2 *Environmental Cultures, Using Same Technic as That in Figure 1, from the Vicinity of an Asymptomatic Ambulatory Pharyngeal Carrier (Nose Cultures Negative, and Throat Cultures Strongly Positive)*

A demonstrates culture of blankets on bed (900 streptococci), B culture of comforter (500 streptococci), C culture of blouse (negative), D culture of overcoat (100 streptococci), and E culture of floor dust immediately surrounding and beneath bed (100 streptococci).

the beds of nasal carriers yielded an average of 66 per cent more streptococci than those of pharyngeal carriers, furthermore, the same type was recovered from nasal carriers and bedding in 74 per cent of cases, as contrasted to only 30 per cent of pharyngeal carriers. The streptococcal content of bedding

belonging to both types of carriers was significantly greater when the same type was recovered from carrier and bed, as might have been expected.

Further studies of the environment of individual nasal and pharyngeal carriers in barracks, in whom the approximate duration of the carrier state was known, demonstrated again the hundredfold difference in amount of streptococcal dissemination to the environment (Fig 1 and 2), and in several cases the nasal carriers were observed to initiate a localized barracks epidemic caused by their own type of streptococcus.²⁷⁻²⁸ It was also found that if the nasal carrier state persisted for four to six weeks, these dispersers could continue to be distinct hazards to their barracks mates, especially if they were transferred to another barracks whose personnel had not been previously exposed to their strain.

The numbers of air-borne streptococci were found to be directly dependent on the presence or absence of nasal carriers of beta-hemolytic streptococci, both in hospital wards and in Army barracks. Over twenty-five times as many streptococci were recovered from the air of a ward housing patients with strongly positive nasal cultures as from the air of a similar ward housing tonsillitis-pharyngitis patients with positive pharyngeal cultures only.²⁹ In the barracks, whenever large numbers of hemolytic streptococci were recovered from the air (up to 100 to 150 per cubic foot), a nasal disperser of streptococci was identified in the personnel.²⁹

The majority of traceable hospital cross infections were found by Hamburger to be due to nasal carriers on the wards. Almost all patients who spread infection had high streptococcal outputs as measured by the patch test (from 40,000 to 500,000 organisms) whereas the majority of patients who failed to spread infection had less than 40,000 streptococci on the most highly contaminated patch. Eleven of 12 cases of ward cross infection were traced to nasal carriers, and only 1 to a pharyngeal carrier. A food-borne streptococcal epidemic was traced to a food handler with a strongly positive nasal culture who handled pies in the incubation period of the pharyngitis; cultures of the hands yielded 10,000,000 organisms of the type responsible for the epidemic.²⁹ As mentioned above, barracks epidemics were traced to single nasal dispersers among the personnel. One asymptomatic nasal carrier caused 10 cases to be admitted to the hospital from his barracks in two weeks. He was hospitalized for another three weeks for study of the streptococcal output and treated for five days with full doses of sulfadiazine, during his hospital stay he acquired another streptococcal type and was still carrying large numbers of streptococci in his nose on discharge. The new type was not present in any of the personnel of the new barracks to which he was assigned, within a few days he had heavily contaminated the bedding, floor dust and air of both floors of this barracks, and induced an epidemic of

streptococcal cross infection involving 30 per cent of the personnel. Four patients who carried the new type of streptococcus were admitted to the hospital from this barracks during the next two-week period. Extensive environmental contamination was found to precede the appearance of cross infections.²⁹ This patient illustrates the fallacy of present-day quarantine regulations and the role that the hospital itself may play in the dissemination of streptococcal disease among the population it serves.

Finally, the nasal carrier rate of troops was found to correlate well with the rates for streptococcal disease. In units having a low incidence of streptococcal disease (0.4 per cent of personnel hospitalized in a six-week period) the nasal carrier rate was 0.13 per cent, or 1 for every 41 pharyngeal carriers. Units having a moderately high incidence of streptococcal disease (5.7 per cent of personnel hospitalized) showed a nasal carrier rate of 4.2 per cent, or about 1 nasal carrier out of every 4 throat carriers. Under epidemic conditions in which nearly a third of a unit was hospitalized in this period, 40 per cent of the population were found to be nasal carriers, or four fifths of all the throat carriers.³⁰ These figures can be compared with the incidence of nasal carriers of streptococci among hospital admissions for pharyngitis or scarlet fever, which ranged from a quarter to two thirds of the cases.^{30, 31}

In view of the obvious importance of the nasal streptococcal disperser, numerous studies were carried out to define more clearly the factors in the individual patient that determined the presence or absence of a profuse growth of streptococci in the nose. It should be emphasized that almost all nasal carriers yield strongly positive pharyngeal cultures. It appears from routine repeated surveys of populations that the nasal carrier state is a far more transient condition than the pharyngeal carrier state, occurring in the first few days or weeks after the patient has acquired a new streptococcal type. Clinical disease may or may not follow the appearance of streptococci in the nose and throat. Occasionally, streptococci have been found only in the nose and not in the throat,^{32, 33} but usually within twenty-four to forty-eight hours when the cultures were repeated the throat was positive. The same type of streptococcus is almost always present in both locations. Proliferation of streptococci in the nose may or may not be associated with coryza or symptoms and signs of paranasal sinusitis.

The majority of so-called "healthy carriers" found by surveys gave a history of recent sore throat, cough or nasal discharge, but signs of tonsillitis and sinusitis were not frequent. Many showed a moderate degree of pharyngeal injection, but no reliable distinction could be made at any time on a clinical basis between this group and the non-carriers. Most of the nasal carriers discovered by cultural surveys did not report to sick call at any time, and the rest were usually returned to duty

by the dispensary physician.²² In spite of the mildness of the signs and symptoms, evidence was obtained of a rising or elevated antistreptolysin titer in 50 to 70 per cent of the ambulatory nasal carriers, and it was concluded that in most cases they represented missed cases of infection rather than true contact carriers with only a symbiotic disease state. It should be emphasized that some of the most "dangerous" of these carriers complained of few symptoms.

Among patients hospitalized with positive nasal cultures the majority had a follicular tonsillitis or severe pharyngitis, and in this group about 60 per cent of cases showed roentgenologic evidence of sinus disease.²⁰ The streptococcal output, however, did not depend on the presence or absence of sinus involvement, and one must conclude that in many cases marked proliferation of streptococci occurs on the nasal mucosa alone. It seems likely that the development of immunity to the infecting strain can be fairly well correlated with the decline in streptococcal output of many of these carriers and with the gradual return of the nasal mucosa to its normal streptococcus-free state. Within ten days after admission the streptococcal output of 80 per cent of hospitalized nasal carriers fell to low levels, and two months later only 13 per cent of these patients carried any streptococci in the nose, although half were still pharyngeal carriers. Many barracks carriers showed an even shorter duration of the nasal carrier state.

Since the symptoms of the ambulatory nasal carrier may be mild and nonspecific, however great their streptococcal output, their control assumes corresponding importance and difficulty. Cultural surveys, which are the only sure method of selecting these cases out of the herd, may be performed rapidly by the placing of the streakings of nasal swabs from 4 cases on quadrants of a single blood-agar plate. Two to 4 patients can be cultured a minute, depending on the amount of teamwork. Presumptive identification of these cultures is much easier than that of the pharyngeal cultures, especially when large numbers of organisms are recovered.²⁵

The chemotherapeutic control of ambulatory nasal carriers has been temporarily successful both with prophylactic doses of sulfadiazine (in the absence of a large proportion of resistant strains) and with calcium penicillin in oil and beeswax (Romansky formula). Sulfadiazine therapy (10 gm daily or more), which clears the nose in two thirds or more of asymptomatic carriers and even in patients may markedly lower the streptococcal output to a safe level, should be carried out for at least three weeks to prevent relapse in many carriers after cessation of therapy. Calcium penicillin given in one dose of 300,000 units a day in oil and wax was found to be much more effective in eradicating streptococci from both the nose and the throat in patients, but half the cases showed a relapse with the same type

after five to seven days of therapy. One quarter of the total again manifested strongly positive nose-blow cultures one to five days after termination of therapy. This period of therapy seems to have been too short for adequate control of patient carriers.³³

DISCUSSION

The importance of the nasal carrier of hemolytic streptococci has been referred to by numerous workers in the field of streptococcal epidemiology. Among the first to utilize nasal cultures were Meleney and Stevens,³⁴ who, in 1926, reported an epidemic of post-operative streptococcal wound sepsis that was traced to the instrument nurse, a nasal carrier. There were several other possible sources for infection from pharyngeal carriers on the surgical staff, but careful serologic analysis utilizing reciprocal agglutination and agglutinin absorption confirmed the identity of one of the wound strains and that isolated from the nurse's nose. In 1933 Colebrook³⁵ was impressed with the possible role of nasal carriers in the production of puerperal sepsis, because of the increased potentialities for contamination of the hands by handkerchiefs, and cites several cases in which nasal carriers seemed to be the source of infection. Hare,³⁶ in 1941, first demonstrated that nasal carriers expelled more streptococci than throat carriers, noting in 3 cases that the contamination of the person was more widespread and of longer duration than when only the pharynx was involved. In 1944 Coburn³⁷ reported two outbreaks of streptococcal disease traceable to post-infection carriers who had clinical and roentgenologic evidence of sinus involvement, nose cultures were not performed. Gordon,³⁸ in 1932, observed that discharged scarlet-fever patients with rhinitis or sinusitis were more likely to transmit infection than patients without complications, or those with other complications, such as suppurative otitis media. The relative lack of infectivity of simple pharyngeal carriers noted above confirms the conclusions of Bloomfield and Felty,³⁹ who in 1923 observed the paucity of cross infection between chronic pharyngeal carriers and normal persons rooming together.

The finding that the nasal streptococcal carrier is in most cases an "acute" carrier who has only recently acquired the organism and from whom dispersion of streptococci gradually diminishes as local or general immunity develops re-emphasizes the conclusions drawn by Blake⁴⁰ after World War I regarding the importance of acutely infected individuals in the genesis of epidemics. Although Bloomfield and Felty's study emphasized the local parasitism of the tonsil by hemolytic streptococci under conditions of sporadic disease, vast and bitter experience has repeatedly shown that virus diseases affecting the upper respiratory tract, especially influenza and measles, predispose to secondary infection with the streptococcus, which then readily

invades on a wide scale the mucosa of the upper and lower respiratory tract.⁴¹ In view of Glover's⁴² production of nasal dispersers of streptococci in ferrets doubly infected with influenza A virus and Group C streptococcus, it would be extremely interesting to know what proportion of acute nasal streptococcal carriers have had their respiratory mucosa already damaged by influenza virus or the virus of the common cold. These ferrets proved highly contagious when placed in close association with other healthy ferrets, and it was shown that administration of streptococci alone infected only the tonsils of the animals, but not the nasal membranes. Infection of the membranes with streptococci was possible only by means of an antecedent or concomitant virus infection.

Since the chemotherapeutic control of nasal dispersers by any means except mass prophylaxis presupposes routine carrier surveys at close intervals (ideally, twice weekly), the use of less cumbersome and protracted safeguards appears to be indicated. Hand contamination from the nose seems to be the most important route of dissemination, and much use could therefore be made of oiling procedures for all handkerchiefs, masks, towelings, bed linen, blankets and clothing with which patients and carriers might come in contact. These procedures have been adapted to standard laundry use and are cheap, nonirritant and safe from fire hazard. The treated textiles cannot be distinguished from those untreated, although the process permanently impregnates woolen fabrics.⁴³ These oiling procedures have been shown to prevent the major portion of secondary contamination of air and dust resulting from streptococcal carriers.¹² Air disinfection with glycol vapors has been shown to enhance the effect of oiled bedding in reducing streptococcal aërial pollution.¹⁴

As Hamburger^{30, 33} suggests, it seems logical to set up new criteria for the discharge of patients with streptococcal tonsillitis from hospitals, regardless of the presence or absence of a rash. No patient should be discharged who has a strongly positive nasal culture, and all such patients should be carefully isolated or given adequate suppressive chemotherapy. Probably, most patients with only a few colonies in the nose cultures could be discharged after three weeks in the hospital, provided that there were no known susceptibles such as young children or patients with rheumatic fever in the home environment. Proper instruction concerning cleanliness of the hands and disposal of nasal secretion would be an additional safeguard. At least two nose cultures prior to discharge should be obtained, preferably at least forty-eight hours or more after discontinuance of chemotherapy.

There is evidence that other bacteria causing upper respiratory infections are disseminated from the nose in a manner similar to that by which the hemolytic streptococcus is spread. For instance,

nasal diphtheria has been regarded by Place⁴⁴ as "by far the most contagious, as discharge through methods and habits of handling may be readily spread about by contact, handkerchiefs, towels, laboratories, candy, toys, hands, garments, etc. Moreover, nasal cases very often escape early detection, under the guise of colds, and allow a longer period of contact than other forms." Localized diphtheria epidemics have been traced to nasal carriers of the same type.⁴⁵ Ward and Henderson,⁴⁷ in 1907, were not able to control a diphtheria epidemic until they had isolated the nasal as well as the pharyngeal carriers among the population.

Similarly, it is thought that the spread of *Staphylococcus aureus* can best be related to its presence or absence on the nasal mucosa, from which the hands are secondarily contaminated. Miles and his co-workers⁴⁸ studied the relation of nasal staphylococcal carriers to wound infection and the bacteriology of the carriers' skins, noting carrier rates of 40 to 50 per cent, with many nasal carriers yielding positive skin cultures. It was possible to prove similarity of types in the nose and on the hands by the phage typing technique in a limited series, and the conclusions were that the hands were the main source for dissemination of coagulase-positive staphylococci from the nose.

Contamination of the hands by staphylococci and streptococci from nasal sources may explain some of the epidemics of food-borne disease caused by these organisms reported from military and civilian sources in the past few years.⁴⁹ It is well to remember that organisms from the upper respiratory tract of food handlers may be just as dangerous as intestinal pathogens when opportunity occurs for food contamination, and, in addition, much of the intra-familial spread of beta-hemolytic streptococci may occur by this route.¹⁵ Transmission of streptococci by hand-to-mouth contamination (or via fomites) seems to be particularly important in children. As a result of observations on the inadequate sterilization of mess kits during the influenza pandemic of 1918-1919, Cumming and Spruit⁵¹ stressed the significance of streptococci and pneumococci on the hands and in the wash water in explaining the high incidence of secondary bacterial infection among troops in World War I. They noted beta-hemolytic streptococci in the mess-kit wash water in 84 per cent of examinations and on the hands of 38 per cent of military personnel. Their studies, which included observations on the experimental transmission of mouth-inoculated *Serratia marcescens*, tended to show a lower incidence of pharyngeal streptococcal carriers and a reduced incidence of influenza and measles among troops boiling all their mess gear as contrasted with a carefully selected control group with inadequate wash-water temperatures.⁵² It is well to recall these studies to emphasize the varied routes that upper respiratory pathogens may take in passing from person to person.

Finally, it should be remembered that the simple pharyngeal carrier of beta-hemolytic streptococci always represents a hazard to his fellows, different from that arising from a nasal carrier only in degree. Much of the sporadic transfer of streptococci probably takes place chiefly from the pharyngeal carriers, as the very low incidence of nasal carriers under these conditions attests.

SUMMARY

There is at present ample evidence that the "strongly positive" nasal carrier of beta-hemolytic streptococci disperses approximately one hundred times the number of organisms to his environment as the pharyngeal carrier, irrespective of the presence of a rash or the severity of the symptomatology. Most of the nasal carriers represent cases of streptococcal infection in the acute phase so far as can be determined by clinical and immunologic evidence, although in many cases symptoms are so mild that they are overlooked or neglected. Probably less than 10 per cent of these carriers continue to disperse large numbers of streptococci for periods longer than two or three weeks. Such carriers as these, however, may initiate localized outbreaks of streptococcal disease, and when acute nasal carriers are multiplied as a result of cross infection, the incidence of clinical disease will rise sharply, with a secondary rise in the pharyngeal carrier rate representing contact carriers and convalescent cases with persistent parasitism and slight potentiality for production of secondary cases. Widespread and lasting control of the proliferation of streptococci on the nasal mucosa is one of the chief problems in the prevention of epidemic streptococcal disease today.

Chemotherapy with sulfadiazine (in the absence of resistant strains) or penicillin, newer technics of environmental dust control with oil and air sanitation using germicidal vapors have been shown to have definite value in reducing possibilities for cross infection offered by nasal streptococcal dispersers.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

CASE 33521

PRESENTATION OF CASE

A fifty-year-old woman was admitted to the hospital because of abdominal pain.

One week before entry, two hours after a normal bowel movement, the patient was suddenly seized with severe persistent lower abdominal crampy pain, and a few hours later she began to vomit. A physician gave her some pills, following which she passed some gas, but the pain persisted throughout the abdomen and she continued to vomit. She was then taken to another hospital, where a Miller-Abbott tube was passed. This lessened the distention, and she stopped vomiting.

Twenty-three years before entry and again three years later, the patient had full-term normal deliveries but had had a great deal of pain throughout both pregnancies. For this reason she was sterilized six years after the last pregnancy by the removal of the tubes and one ovary, the appendix was also removed. The menopause occurred nine months before admission, and she had subsequently had only intermittent bleeding.

Physical examination revealed a slightly distended "doughy" abdomen with active peristalsis. There was a freely movable, nontender golfball sized mass in the left midabdomen. Vomiting had ceased. She passed gas by rectum, and an enema gave good results.

The temperature was 98°F, the pulse 90, and the respirations 22. The blood pressure was 118 systolic, 70 diastolic.

The red-cell count was 4,660,000, with a hemoglobin of 11.4 gm and a hematocrit of 39 per cent.

The white-cell count was 11,200, with 87 per cent neutrophils. The serum chloride was 85 milliequiv per liter. The serum protein, the nonprotein nitrogen, the fasting blood sugar and the prothrombin time were within normal limits.

An x-ray film showed the tip of the Miller-Abbott tube in the left midabdomen, with dilated loops of small bowel both proximal and distal to the tip.

The day after admission the dilated loops proximal to the tube were no longer visible, whereas those in the right lower quadrant close to the cecum persisted. On the third day the tip of the Miller-Abbott tube was still in the same position. Injection of 50 cc of barium through the tube revealed knuckling and narrowing of the small bowel to a width of 1.0 cm or less. There was no evidence of prominence of the mucosa. The loops of bowel immediately proximal and distal to the tip were not dilated. A film taken four hours later showed the barium to have stopped in the same loops, and the persistent dilated loops of small bowel were noted in the right side of the abdomen.

The patient was treated with Amigen, vitamin B₁, hykinone and intravenous 5 per cent dextrose in saline solution. The chloride increased to 94 milliequiv per liter, and the hematocrit and hemoglobin were reduced to 34 per cent and 9.4 gm respectively.

An operation was performed on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR CLAUDE E. WELCH: This is an obvious case of intestinal obstruction. One of our major problems is to determine the site of the obstruction. Clinically the best clue is the location of the pain. The patient had severe lower abdominal crampy pain, which usually means that the colon is involved rather than the small bowel. However, when a patient begins to vomit shortly after the attack of cramps, obstruction is presumed to be in the small bowel rather than the large, and the repeated vomiting is evidence more in favor of small-bowel than large-bowel obstruction. Since the character of the pain during the pregnancies is not described I am unable to make much out of this symptom.

"She was sterilized six years after the last pregnancy by the removal of the tubes and one ovary." This might suggest, is an unusual method of sterilization, and implies that there was something

wrong with the pelvic organs at that time requiring removal of the ovary

"The menopause occurred nine months before admission, and she had subsequently had only intermittent bleeding" That is a confusing statement, and is impossible to interpret

One should pay attention to masses, even though they are very small, but because of its character I shall say that this so-called mass was the distended balloon of the Miller-Abbott tube I may be wrong, but it seems to fit better with the history

There is no note of vaginal or rectal examinations In trying to abstract some of these histories it is difficult not to leave out some of the important points, but I think that we are justified in assuming that those examinations were made and were negative

The blood studies showed evidence of dehydration as brought out in the latter part of the record There was a slight leukocytosis, with an increase of neutrophils, but not enough to be of great significance The serum chloride was low because of the repeated vomiting It would have been interesting to know whether the stool that was obtained by enema was guaiac positive or negative That specimen probably eluded the watchful eye of the nurse on the ward and was disposed of before it reached the laboratory

May we see the x-ray films?

DR STANLEY M WYMAN The first examination shows dilated loops of small bowel assuming a lace pattern There is some barium remaining in the colon from a previous examination, and there is gas extending up to the region of the splenic flexure The film taken the next day shows some decrease in distention of the small bowel, but the tip of the Miller-Abbott tube is not changed in position The position of the tube is constant throughout the series of films Two days after the first film barium was introduced into the Miller-Abbott tube, and the spot films taken at the time of examination show the tip of the tube in the apparent area of narrowing at this point in the small bowel It is rather hard to interpret this without having done the examination There is no definite evidence of a change in the mucosal pattern This is a loop of dilated small bowel just distal to the tube, so that there is at least one point of narrowing in the small bowel without apparent involvement of the mucosa

DR WELCH Do you see any evidence of air in the liver radicles?

DR WYMAN There is no evidence that I can see of gas extending up into the liver shadow

DR WELCH You can see nothing that suggests a shadow of calcium rather than barium in the lower bowel?

DR WYMAN I do not see any stones scattered through the abdomen I think that there is at least

one point of narrowing in the small bowel that does not involve the mucosa, so far as I can tell

DR WELCH The x-ray examination has been very helpful in many respects. Even if he had done the examination, I imagine that Dr Wyman would agree that it would be difficult to interpret the spot films

When faced with a case of intestinal obstruction, the surgeon must attempt to be more specific and attempt to name the causative factor of the obstruction The first question is to determine whether the large bowel or the small bowel is involved In this case the x-ray examination has been of great value because the barium studies have shown a fairly normal colon with no distention, indicating that the lesion involves the small intestine The surgeon must next determine whether a strangulating or a nonstrangulating obstruction is present Strangulating obstruction is identified by the presence of tenderness, by the absence of peristalsis and often by leukocytosis A patient with this type of obstruction must be operated on promptly. Obviously, a strangulating obstruction was not present in this case, so that we immediately rule out the strangulating lesions of the small bowel producing obstruction, which include intussusception, mesenteric thrombosis and volvulus Consequently, we pass on to the nonstrangulating types To begin with, there are a few rather unlikely lesions of the small bowel that can be excluded immediately It is unlikely that this patient had an inflammatory lesion of the distal ileum I assume that the statement in the x-ray interpretation that there was evidence of prominence of the mucosa is meant to indicate no evidence of regional ileitis Is that correct?

DR WYMAN I should think so.

DR WELCH It would be unusual for regional ileitis to appear with the first symptoms at fifty years of age and then with acute obstruction The same statement is true of other types of inflammatory diseases in the distal ileum What, then, are the common and likely causes of the obstruction in this patient? If one can judge by percentage figures, hernia, either obvious or concealed, should be the most obvious choice A careful examination was made of this woman, and the chances that a hernia was undiscovered are rather slight A femoral hernia is often hard to find and may be overlooked However, that is unlikely In the presence of operative scars, bands or adhesions furnish by far the most frequent causes of intestinal obstruction and, until we can discover a better cause, must be considered seriously

The next thing to be considered is a foreign body In this part of the country, where persimmons are not a favorite part of the diet, the only foreign body that commonly obstructs the small bowel is a gallstone That is a difficult diagnosis to make, especially in the absence of signs pointing to the gall bladder There was no gas in the biliary radicles and no evidence of stone by x-ray examination

The third most probable cause to be considered is that of tumor involving the bowel. It is unlikely that this was a primary carcinoma of the ileum. The obstruction came on suddenly, and there was no evidence of bleeding by rectum. Our attention has been called to a mass, and that might be interpreted as tumor of the small bowel. I believe that we have a much better right to call it a distended Miller-Abbott tube. Could this have been one of the peculiar benign tumors of the lower portion of the small bowel, such as carcinoid? Again, there is no evidence in its favor, its rarity rules this diagnosis out as a likely possibility.

Could the patient have had metastatic carcinoma arising somewhere in the abdomen and involving the terminal portion of the small bowel, especially at the multiple points of obstruction suggested by x-ray study? It is possible, but again in a woman the usual source of such a carcinoma is in the ovary and we have the right to assume that the pelvic examination had been negative.

Since we have to make a diagnosis in this case of intestinal obstruction, I believe that it is obstruction of the small bowel, in the lower ileum, nonstrangulating in type, due to bands from the previous operation.

CLINICAL DIAGNOSIS

Intestinal obstruction

DR. WELCH'S DIAGNOSIS

Intestinal obstruction, due to adhesive bands

ANATOMICAL DIAGNOSES

Acute oophoritis and perioophoritis

Intestinal obstruction, due to inflammatory adhesions

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY. I am sorry that the surgeon who operated on this woman is not present to discuss the diagnostic problem. So far as the record is concerned he did not commit himself beyond the diagnosis of intestinal obstruction.

The patient was explored, and several coils of small bowel were found adherent to a mass lying at the brim of the pelvis. The adhesions were fibrinous, and it was possible to separate them with blunt dissection. When that was done, it was found that the mass was a considerably enlarged ovary measuring 7 cm. in diameter, the center of which was filled with pus. The ovary was removed, and following operation the patient made a rapid convalescence. Inasmuch as the uterus and both tubes had been removed fourteen years before, I believe that we are safe in assuming that this was a hematogenous infection of the ovary.

CASE 33522

PRESENTATION OF CASE

First admission. A fifty-one-year-old housewife was admitted to the hospital because of shortness of breath.

Twenty-nine years before entry she had an attack of rheumatic fever characterized by pain and swelling of the wrists and hands. She was put to bed for three months. After this she felt well and had two children. She was told, however, that her heart was weak, and eighteen years before entry her last pregnancy was terminated for this reason. Two years before entry she began to have dyspnea on exertion, requiring bed rest occasionally for a day or two. Recently she had to use two pillows at night. Two weeks before entry she "contracted a cold" with cough and daily expectoration of several tablespoonfuls of foamy, sometimes blood-stained sputum. She became extremely dyspneic and orthopneic, and was treated with digitalis, Mercupurin and penicillin with doubtful improvement. On the night before admission she became worse, with severe cough and orthopnea.

Physical examination revealed an orthopneic woman, with some cyanosis and malar flush. The neck veins were distended and pulsating. There were basal rales on both sides of the chest. An examination of the heart was reported as follows:

The heart is tremendously enlarged to the left and right, with the point of maximal impulse at the fifth interspace at the anterior axillary line. There is enlargement to the right in the fifth space, with the right border of dullness 5 cm. from the midsternal line. There are sounds of good quality. The mitral first sound is strong and booming and the pulmonary second sound is very much increased and duplicated. At the apex there are Grade IV systolic and diastolic murmurs with an accompanying thrill. The systolic murmur is loud and harsh through all of systole and is transmitted to the back. The diastolic murmur is very loud and low pitched and occupies all of diastole, with the strongest element in mid diastole. In the right lower portion of the chest anteriorly, over the upper border of the liver, there is a very loud Grade III or IV rough systolic murmur with a thrill. At the base no murmurs that can be separated from the widely transmitted ones noted above can be made out. The rhythm is totally irregular.

The liver edge was palpated 10 cm. below the costal margin and was firm. The spleen was felt 2 cm. below the costal margin. No abdominal fluid was detected. There was only minimal pitting edema of the ankles.

The temperature was 101.4°F., and the pulse 96. The blood pressure was 120 systolic, 80 diastolic.

An electrocardiogram showed auricular fibrillation, the ventricular rate averaging 100. The QRS complex was 0.09 second, with normal voltage, right-axis deviation, absent R, prominent QS and very low T waves in Lead I, sagging ST segments in Leads 1, 2 and 3, slightly inverted T waves in Lead 3, small R and prominent S waves in

Leads CF_1 and CF_2 and upright T waves in Leads CF_3 , CF_4 and CF_6 . There was one ectopic ventricular beat

X-ray examination of the chest revealed that the heart was enormously enlarged in all directions, the transverse diameter being 22 cm and the chest 25.5 cm. There was calcification of the arch of the aorta. The left auricle appeared extremely large, pressing on the left main bronchus and compressing

FIGURE 1

it posteriorly. There was fluid in both pleural cavities. The hilar shadows were prominent (Fig 1).

Examination of the blood disclosed a hemoglobin of 14 gm and a white-cell count of 12,000, with 90 per cent neutrophils. The sedimentation rate was 14 mm in 1 hour (corrected). The prothrombin time was normal. The van den Bergh reaction was 0.8 mg per 100 cc direct and 1.4 mg indirect. The cephalin-flocculation test was +++ in forty-eight hours. The urine showed a + test for albumin, with an occasional hyaline cast in the sediment. The stools were guaiac negative.

The patient was treated with penicillin, a low-sodium diet, ammonium chloride and Purodigin. She had an episode of severe dyspnea and pain in the right side of the chest the day after admission. Following this her condition improved steadily. The temperature, pulse and respirations were normal, and the chest rales cleared. After two weeks she was discharged to a nursing home on a maintenance dose of Purodigin.

Second admission (five weeks later). The patient was readmitted because of severe dyspnea and chest pain. In the interval she had stayed in bed most of

the time. For two weeks prior to readmission she had sharp pains in the right axilla, aggravated by cough and respiration. On the day before readmission she had a "cold," and around supper time, she suddenly developed a persistent cough and foamy, white sputum. The dyspnea and pain in the right side of the chest became very severe, and she had to sit up in bed all night. By morning she felt feverish and had noticed some blood staining of the sputum.

Physical examination revealed dyspnea, cyanosis and cough. The temperature was 103°F. There were rales in both sides of the chest but no signs of consolidation or fluid. There was a transient friction rub in the left axilla. The heart signs were the same as on the previous admission. The rate was irregular with a pulse of 90 and a blood pressure of 115 to 120 systolic, 70 to 80 diastolic. The liver edge was palpated four fingerbreadths below the costal margin and was pulsating. There was shifting dullness in the flanks and bilateral ankle edema, more on the right side. There was no calf tenderness or pain on dorsiflexion.

Examination of the blood disclosed a red-cell count of 4,100,000, with a hemoglobin of 14 gm, and a white-cell count of 8200, with 88 per cent neutrophils. The urine showed a specific gravity of 1.018, with a ++ test for albumin. The sputum was negative for pneumococci. An electrocardiogram was similar to that on the previous admission.

A bilateral femoral-vein ligation was done on the second hospital day. The congestive failure rapidly subsided with digitalis and Mercupurin, and after the fifth hospital day, the temperature remained normal. The patient was discharged at the end of two weeks on a low-sodium diet, digitalis, ammonium chloride and Aminophylline suppositories.

Third admission (five weeks later). The patient returned to the hospital because of an incarcerated femoral hernia. A herniorrhaphy was done, and 13 cm of infarcted ileum was resected. She made a good recovery and was discharged eighteen days later on a regime of digitalis, ammonium chloride, a low-sodium diet and mercurhydrin intramuscularly.

Fourth admission (six weeks later). Because of the gradual onset of additional symptoms of feverishness, night sweats, shoulder pains and malaise, the patient was readmitted. There were no chest, abdominal or back pains, gross hematuria, chills, pains in the fingertips or petechiae.

The physical examination was essentially similar to that on previous admissions except that the examiner noted systolic murmurs at the base on each side of the sternum, in addition to the apical murmurs and those in the right side of the chest. The spleen was firm, tender and palpable 3 cm below the costal margin. There was only slight ankle edema.

The temperature was 100°F.

An x-ray film of the chest revealed some fluid in the right pleural sinus. The electrocardiogram was unchanged.

The hemoglobin was reduced to 10 gm. The red-cell count was 3,000,000, and the white-cell count was 7100. A cephalin-flocculation test was +++ in twenty-four and forty-eight hours, and the brom-sulfalein test showed only 4 per cent retention of the dye. Repeated blood cultures were negative. The urine gave a + test for albumin.

The patient was hospitalized for sixteen days and during that time the temperature ranged from 98° to 100°F, the pulse from 70 to 80, and the respirations from 20 to 30.

Final admission (eight weeks later) The patient had been reasonably well until the midnight before entry, when she complained to her daughter that she felt as though the blood were rushing to her head, and asked to go to the bathroom. The daughter helped her to the bathroom, and on returning the patient rather suddenly became severely short of breath and cyanotic and was unable to speak. There was no unconsciousness, convulsive movements or incontinence.

Physical examination revealed a cyanotic, dyspneic, slightly confused woman with a temperature of 100°F. The neck veins were distended and pulsating. The heart was fibrillating at a rate of 95 per minute (apical), and the blood pressure was 150 systolic, 90 diastolic. The lungs were resonant throughout. The respiratory sounds were faint, and there were tight expiratory wheezes over the entire chest. There were moist inspiratory rales at both bases, more on the right. The liver edge was palpated three to four fingerbreadths below the costal margin and was firm and sharp. The spleen was not felt. There was a +++ pitting edema of both ankles. There was flaccid paralysis of the right lower part of the face and the right arm and leg, as well as questionable aphasia. The deep tendon reflexes were equal on both sides. Babinski and Chaddock signs were suggestive on the right. The neck was not stiff.

The white-cell count was 7100, with 83 per cent neutrophils. The hemoglobin was 11 gm. The urine showed a ++ test for albumin. The cerebrospinal fluid contained 200 red cells per cubic millimeter in one tube and 500 red cells in the other.

The patient was given oxygen, Cedilamid and mercurazanthin. The next day she developed dullness and almost absent breath sounds in the right middle and lower lobes, and the white-cell count increased to 16,100. An emergency bronchoscopy was done, and this increased the breath sounds and aeration temporarily although an obvious plug of secretion was not removed. Tracheal rales were soon heard over the entire chest. She became exhausted and unresponsive and died quietly two days after admission.

DIFFERENTIAL DIAGNOSIS

DR COLESBY PAUL May we start by seeing the x-ray films?

DR STANLEY M WYMAN The huge heart described is seen to be essentially unchanged from the first observation until six months later. It is enlarged both to the right and to the left, the greater enlargement seems to be toward the right. There is a small quantity of fluid in both pleural spaces. The left oblique view shows the left main bronchus elevated, compressed and narrowed by what I take to be a huge left auricle. The right oblique view again shows a large left auricle. There is calcification of the aortic arch well over to the right. No note is made by fluoroscopy of calcification in the heart itself. I cannot see any on the film. Later films show the fluid in the right pleural space to have increased considerably five months after the first film. There is no very good evidence of enlargement of the region of the left ventricle.

DR PAUL It would be very hard to make a diagnosis of pulmonary infarction with a heart of that size, would it not?

DR WYMAN Yes.

DR PAUL Starting with the first admission, we have no reason to question the fact that this patient had had rheumatic fever in the past leading to severe rheumatic heart disease. The question is, What had changed the course from one of fairly good tolerance of effort to one of sudden appearance of congestive failure? Several things should be considered. She may have developed auricular fibrillation or flutter, or she may have had a reactivation of rheumatic fever or developed some other infection, perhaps even bacterial endocarditis. A third possibility is that of pulmonary infarction. It is interesting that when she came in, she was in severe failure. The murmurs can be interpreted as indicating mitral stenosis and marked mitral regurgitation; the question arises, What was the murmur in the right lower portion of the chest anteriorly over the liver area? That may have been the murmur of mitral regurgitation well heard in the right side of the chest because the left auricle extended so prominently to the right. Ordinarily, I suspect that it is better heard posteriorly and in the axilla than anteriorly. A less likely possibility is that it represented the murmur of aortic stenosis. The splenic enlargement does not necessitate a diagnosis other than rheumatic heart disease and congestive failure. Occasionally, we see patients in congestive failure who do have palpable spleens, without other evidence of bacterial endocarditis. It should raise the possibility of bacterial endocarditis but does not necessitate making that diagnosis.

The electrocardiogram is consistent with mitral stenosis. The absence of apnea on the first admission is of course some evidence against rheumatic heart disease and bacterial endocarditis. The patient

was considered on the first admission to have infection, not rheumatic in type, for she was given penicillin and did improve. It seems probable in view of the second admission that she actually had repeated episodes of pulmonary infarction, and following ligation of the femoral veins bilaterally she appears to have done well for a time.

The first two admissions may therefore be explained on the basis of severe rheumatic heart disease complicated by multiple pulmonary emboli.

We do not need to go into the third admission, when a herniorrhaphy was performed, except to say that despite marked valvular disease, the patient showed good tolerance for major surgery. Nothing else is indicated in that note to show any new findings.

The fourth admission is interesting. For the first time the patient complained of persistent fever, sweats and general malaise, and for the first time she was anemic. When she was admitted, she showed less evidence of failure than she had on previous admissions, and had no leukocytosis. There were no positive joint findings, although it is stated that there were joint pains, and no nodules, petechiae, clubbing of the fingers or weight loss were mentioned. The pulse was not rapid. It is stated that repeated blood cultures were negative. She was in the hospital for sixteen days, so that there was a considerable period in which cultures could have been taken, apparently, they were negative or showed only contamination.

She was sent home, presumably with a diagnosis of active rheumatic fever. I should think that she would not have been sent home had bacterial endocarditis been seriously considered. No mention of treatment is made, but I gather that there was no other evidence of infection suggesting the need for chemotherapy.

She did reasonably well during the intervening eight weeks. "Reasonably well" is to my mind a tribute to her heart, for with a heart of this size one would hardly expect the patient to do well, especially in view of the fact that in the previous six months, she had had four hospital admissions, two operations and repeated pulmonary emboli. The fact that she did reasonably well suggests that there was no serious infection, particularly bacterial endocarditis. There is no mention of new symptoms.

Finally, she turned up in the hospital for two days with a terminal cerebrovascular accident of some type. Again, at this final admission we are not told that examination showed clubbing or petechiae or enlargement of the spleen. The anemia was, if anything, less than before. (Perhaps the patient was dehydrated.) Certainly, it does not appear that she was more anemic. She finally succumbed with pulmonary complications due to plugging of the right main bronchus.

I believe that the diagnoses until the fourth admission were rheumatic heart disease, mitral stenosis

and regurgitation, possibly involvement of the aortic valve, quite possibly a functional tricuspid regurgitation and old pulmonary infarction. The question now arises, Was the fourth admission related to the final admission when she succumbed? It may have been, for she may have had subacute bacterial endocarditis on both occasions. A diagnosis of active rheumatic fever on the fourth admission and then bland embolism on the final admission do not necessarily bear any relation, however. So far as I know, there is no correlation between rheumatic activity and the incidence of fatal or nonfatal emboli from the left or right auricle.

What is in favor of subacute bacterial endocarditis? The history is classic feverishness, sweats and malaise occurring insidiously, low-grade fever and joint pains (which raise the possibility of associated active rheumatic fever). Joint pains of a vague type are at times described in subacute bacterial endocarditis without other clear evidence of rheumatic activity. The spleen was palpable, and there was a new murmur, as well as a basal systolic murmur not previously mentioned. It is possible that the murmur was a transmission from the Grade IV murmur described at the apex—it was loud enough to have been heard at the base. The absence of leukocytosis is not unusual in bacterial endocarditis. Finally, one could explain the terminal episode as representing the tossing off of an embolus from the vegetations in the heart. There are certain things against that diagnosis, however. The first and most important is that during the eight-week period in which the patient went home following the fourth admission, she apparently did quite well. I believe that if she had had bacterial endocarditis, she would have had a downhill course, at least sufficiently obvious to have deserved reference to symptomatology. I also believe that she would have become more anemic rather than having the blood improve to the extent that it did. Repeated blood cultures were negative. Also on the final admission, the spleen was not palpable and appears to have grown somewhat in size rather than diminished. No weight loss is noted in the history, and there was no clubbing of the fingers. Also somewhat against the diagnosis of bacterial endocarditis is the fact that the patient had marked valvular disease. We more commonly associate bacterial endocarditis with moderate or mild valvular disease than with severe valvular disease. Finally, the combination of auricular fibrillation and bacterial endocarditis in the same patient is not common.

A few remarks about rheumatic fever itself are indicated. She was a known rheumatic patient, and rheumatic activity in an adult is probably more frequent than we appreciate. She did have a low-grade fever, of the type one expects more in rheumatic fever than with subacute bacterial endocarditis. She had joint pains and anemia. She also

improved to some extent in the hospital without chemotherapy, for she was sent home. I would not expect her to have improved significantly on bed rest if she had had bacterial endocarditis. To explain the terminal episode, we must assume that she had an embolus from the left auricle, which was not related to the presence of active rheumatic fever.

On reviewing the evidence I should say that we have more against the diagnosis of bacterial endocarditis than for it. I should like therefore to make a diagnosis of chronic rheumatic heart disease, with mitral regurgitation and mitral stenosis. The patient may have had aortic disease, but I cannot be sure from the evidence at hand. I would not be surprised if a functional tricuspid insufficiency was indicated by the presence of a dilated tricuspid ring, and believe her heart to have been large, with a big left auricle and evidence of old pulmonary infarcts, which may have been found as healed scars at post-mortem examination. I suspect that she had a terminal embolus from the left auricle to the left cerebral hemisphere. I think that subacute bacterial endocarditis is less likely and shall put it as my second choice.

DR. HOWARD B. SPRAGUE: Would you entertain the possibility of adding an interauricular septal defect to explain the fact that she did so well for so long and also to explain the somewhat abnormal transmission of murmurs?

DR. PAUL: I should think the course was consistent with severe rheumatic heart disease alone. The murmurs themselves were probably consistent with that diagnosis.

CLINICAL DIAGNOSES

Rheumatic heart disease, with mitral stenosis and regurgitation
Embolism of left middle cerebral artery

DR. PAUL'S DIAGNOSES

Rheumatic heart disease, with mitral stenosis and regurgitation
Rheumatic endocarditis, chronic, aortic?
Cardiac hypertrophy and dilatation, especially left auricle
Mural thrombus, left auricle
Pulmonary infarcts, healed
Cerebral embolus
Subacute bacterial endocarditis?
Chronic passive congestion of spleen

ANATOMICAL DIAGNOSES

Rheumatic heart disease, with mitral stenosis and insufficiency
Mural thrombus, left auricle
Cerebral embolus, left middle cerebral artery
Endocarditis, chronic rheumatic, slight, aortic and tricuspid
Cardiac hypertrophy and dilatation, especially left auricle
Rheumatic endocarditis, chronic, aortic
Chronic passive congestion of spleen and liver
Renal infarcts, healed

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: At post-mortem examination the heart was enormously dilated but not very much hypertrophied, it weighed 400 gm., which is perhaps 30 per cent above normal for a woman of this size. The cavity of the various chambers was estimated to contain about 100 cc. on the left and 200 cc. on the right, the right auricle contained 300 cc., and the left auricle 1000 cc. The mitral valve was severely stenotic and also probably showed regurgitation. There were only traces of rheumatic involvement on the aortic and tricuspid valves. I should think it doubtful if either of them was functionally inadequate. The lungs revealed comparatively little evidence of chronic passive congestion. There was a scar of an old pulmonary infarct of considerable size. The kidneys likewise showed scars of old healed infarcts, and there was a fresh embolus in the middle cerebral artery, with softening of the left cerebral hemisphere. The source of the embolus was a large thrombus in the enormously dilated left auricle.

DR. RICHARD J. CLARK: What was the size of the spleen?

DR. MALLORY: It weighed 275 gm. That is about an average weight for the spleen of chronic passive congestion and rheumatic heart disease. I doubt if it could have been palpated as described in the record. It is rare that a spleen less than 400 gm. can be felt.

DR. CLARK: Was there any positive evidence of active rheumatic infection?

DR. MALLORY: None whatever, grossly or microscopically.

income Some fellows may mistakenly believe that with the additional increase from the Massachusetts Medical Society members their dues will no longer be required The combined income from the Library's investments and dues and the Massachusetts Medical Society members will just about carry the contemplated increase in services, leaving nothing over for the very necessary completion of seven unfinished tiers of stacks, the refurnishing of Holmes, Sprague and Ware halls and the completion of the also unfinished Periodical Room If money is borrowed for these structural changes (and they are necessary if the Library is to fulfill its mission) it is evident that not only all this income but more will be necessary It follows, then, not only that all fellows must retain their membership but also that more must be acquired

The fellows constitute the legal corporation of the Library, control its assets and real estate and elect its officers When funds are obtained to refurnish parts of the building it is planned to set aside certain rooms for the exclusive use of the fellows To be a fellow of the Boston Medical Library will continue to be a real distinction

SUBSCRIPTION RATE INCREASES

The *New England Journal of Medicine*, after twenty-seven years without an increase in subscription rate, finds it necessary at last to pass on to its subscribers part of the growing cost of publication After January 1, 1948, the regular subscription rate will be \$7 00 per annum

NOTICES

JOSEPH H PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a m

MEDICAL CONFERENCE PROGRAM

Wednesday, January 7 — Histochemical Studies of Blood and Bone Marrow Dr Jack Rheingold

Friday, January 9 — Carcinoma of the Prostate Dr George G Smith

Wednesday, January 14 — Pediatric Clinicopathological Conference Drs James M Baty and H E MacMahon

Friday, January 16 — Diagnosis of Thyroid Deficiency and the Use of Thyroid Hormone Therapy in Infants, Children and Adolescents Dr Nathan B Talbot

Wednesday, January 21 — Recurrent Spontaneous Pneumothoraces and Their Surgical Treatment Dr Francis M Woods

Friday, January 23 — Rheumatic Fever from the Epidemiological and Preventive Points of View Dr David D Rutstein

Wednesday, January 28 — The Tuberculoid Structure. Dr Francis M Thurmon

Friday, January 30 — The Clinical Significance of Various Types of Peripheral Neuritis Dr D Denny-Brown

On Tuesday and Thursday mornings from 9 00 to 10 00, Dr S J Thannhauser will give medical clinics on hospital cases On the second and fourth Friday afternoons of each month, therapeutic conferences will be held from 2:00 to 4 00 with round-table discussion, Dr R P McCombs, moderator, Dr Merrill Sosman will conduct x-ray conferences from 4 00 to 6 00 On Saturday mornings from 9 00 to 10 00 clinics will be given by Dr William Dameshek Medical rounds are conducted each weekday except Saturday by members of the staff from 12 00 to 1 00

All exercises are open to the medical profession

TUFTS ALPHA OMEGA ALPHA

The Tufts chapter of the Alpha Omega Alpha will meet at the Boston Medical Library, 8 Fenway, on Wednesday, January 7, at 8 p m Dr Siegfried J Thannhauser and Dr H Edward MacMahon will conduct a clinicopathological conference

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, January 8, at 7 15 p m in the classroom of the Nurses' Residence The subject, "Subarachnoid Hemorrhage," with a case presentation, will be discussed by Dr Edith D Stanley Dr Eleanor E Cowan will be chairman

Since this is the annual meeting, a full attendance is requested The change of date from January 1 to January 8 should be noted

CONFERENCE ON NORMAL AND PATHOLOGIC PHYSIOLOGY OF PREGNANCY

The Committee on Human Reproductive Research Council, in behalf of the National Maternal Health, will sponsor a conference on normal and pathologic physiology of pregnancy Dr Earl T Engle, assisted by the National Research Council sessions will be held at the Hotel 30 and 31

Among those participating in Arthur T Hétig, Don Wayne Smith and Foster Kellogg and

VOLUME 33
1947

INDEX

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

1947

The date of publication of any case may be determined from the case number. The first two figures of each case number indicate the volume number, 33. The third and fourth figures give the number of the week, dating from January 1. The last figure gives the case number for the week. For example, Case 33251 is the first case for the twenty-fifth week of Volume 33.

- Abscess of brain, 33261
 - multiple, 33082
 - of liver, multiple, 33282
 - mesenteric, 33332
 - with perforation and general peritonitis, 33312
 - myocardial (left ventricle), 33411
 - subdiaphragmatic and subhepatic, secondary to cholecystectomy, 33101
- Actinomycosis of lung, 33052
- Adenocanthoma of cardia of stomach, 33192
- Adenocarcinoma, see Carcinoma
- Adenoma of bronchus, with hemorrhage into lung, 33322
- Adrenal gland, amyloid degeneration of, 33021
- Amyloidosis, adrenal gland, 33021
 - of kidney, 33021
 - of liver, 33021
 - of spleen, 33021
 - of thyroid gland, 33281, 33452
- Aneurysm, arteriosclerotic, rupture of, right iliac artery, with retroperitoneal hematoma, 33502
 - dissecting, with rupture of aorta, 33091, 33121, 33232
 - mycotic, of brain, 33122
- Aorta, see Aneurysm
- Appendix, lymphoma of, lymphoblastic, 33292
- Arthritis, rheumatoid, 33371
- Beriberi disease of heart (probable), 33422
- Bile duct, carcinoma of, 33152, 33291
 - cholangitis of, 33042, 33282
 - intrahepatic, 33362
 - defect of, postoperative, 33042
 - stone in (common), 33282, 33291
- Bone marrow, lymphoma of, lymphoblastic type, 33292
- Bone, tumor of, Ewing's (rib and toe), 33401
 - of fibula, 33161
 - benign giant-cell, of coccyx and sacrum, 33141
- Brain, abscess of, 33261
 - multiple, 33082
 - aneurysm of, mycotic, with subarachnoid hemorrhage, 33122
 - embolism of, 33522
 - glioblastoma multiforme, 33132
 - infarct of, multiple, 33082
 - oligodendroglioma (?) of, 33081
 - (See also Meningitis, Sinusitis)
- Bronchus, adenoma of, 33322
 - papilloma of (basal-cell), with cornification, 33151
- Calcification, metastatic (vitamin D intoxication), of kidney and pituitary body, 33071
- Carcinoid, multiple, of ileum, with metastases to mesenteric lymph nodes, 33222, 33451
- Carcinoma, ampulla of Vater, 33291
 - of bile duct, 33152
 - of gall bladder, with perforation, 33341
 - of jejunum, adeno-, 33201
 - of kidney, squamous-cell, with nephrolithiasis, 33471
 - papillary, 33212
 - of liver (hepatoma), with invasion of cystic duct and metastases to third lumbar vertebra, 33441
 - metastatic (epidermoid) source undetermined, 33072
 - of lung, adeno-, metastatic renal-cell, 33012
 - squamous, 33372, 33432
 - of lymph nodes, adeno-, metastatic, around bile ducts from previously resected carcinoma of rectum, 33262
 - of pancreas, 33491
 - with metastases to liver 33172
 - with extension into and ulceration of stomach, 33472
 - of prostate, 33492
 - of rectum, adeno-, 33432
 - of sigmoid, with perforation, 33112
 - of stomach, multiple polypoid, with metastasis to lymph node, 33171
 - of thyroid gland, giant-cell type, 33512
- Cholangitis, see Bile duct
- Cholecystitis, see Gall bladder
- Choledocholithiasis, see Bile duct
- Cholelithiasis, see Gall bladder
- Chondroma, of knee, 33041
- Chordoma of third lumbar vertebra, 33032
- Cirrhosis, see Liver
- Colitis, see Intestine
- Colon, see Intestine
- Cyst, of pancreas, 33321
 - bronchiogenic, 33461
 - tracheobronchial, of esophageal wall, 33182
- (Diabetes insipidus) 33071
- Diverticulitis, see Intestine
- Duodenum, see Intestine
- Dystrophy, pseudohypertrophic, muscular, 33311
- Embolism, cerebral, 33522
 - mesenteric, 33302
 - multiple, 33301
 - pulmonary, 33491
- Endocarditis, see Heart
- Endometriosis, see Uterus
- Esophagus, cyst of, tracheobronchial, 33182
 - leiomyoma of, 33252
 - ulcer of, peptic, 33501
- Ewing's tumor of fibula, 33161
 - of rib, 33401
 - of toe, 33401
- Gall bladder, carcinoma of, with perforation, 33341
 - cholecystitis, chronic, 33291
 - cholelithiasis, 33291
 - infarct of, 33241
 - lymphoma of, lymphoblastic, 33292
- Heart, abscess of, myocardial, 33411
 - Beriberi disease of (?), 33422
 - Dystrophy of myocardium, pseudohypertrophic, 33311
 - Endocarditis, bacterial, acute, of mitral valve, 33082
 - subacute, aortic, 33122
 - rheumatic, aortic, with stenosis, 33372
 - mitral, with stenosis, 33131, 33372, 33522
 - type undetermined, chronic, mitral and tricuspid, 33272
 - Fibrosis, of myocardium, 33311
 - diffuse, 33422
 - Hypertrophy, marked, ventricle, 33131, 33211
 - Infarct, myocardial, old and recent, 33061
 - Pericarditis, acute, tuberculous, 33391
 - Sclerosis, coronary, 33022, 33061, 33231
 - Stenosis, calcareous, aortic, 33211, 33421, 33511
 - Thrombus, mural, left auricle, 33522
- Hemangioma, cavernous, of lung, 33251
- Hematoma, retroperitoneal, 33502
- Hematometrium, 33402
- Hepatitis, see Liver
- Hepatoma, with invasion of cystic duct and metastases to third lumbar vertebra, 33441
- Hodgkin's disease, see Lymphoma
- Hypernephroma, see Kidney, renal-cell carcinoma of
- Ileum, see Intestine
- Ileus, gallstone, 33202
- Infarct of brain, multiple, 33082
 - of gall bladder, 33241

- of lung 33301, 33491
of myocardium old and recent 33061
Intestine, carcinoid of (ileum) multiple, with metastases to mesenteric lymph nodes 33222, 33451
carcinoma of, adeno- (jejunum) 33201 (rectum), 33432
colloid (sigmoid) with perforation, 33112
colitis of ulcerative, 33021
diverticulitis of (sigmoid), acute and chronic, 33062
gallstone ileus, 33202
leiomyoma of (descending colon) 33392
lymphoma of lymphohistiocytic (jejunum), 33292
obstruction of (ileum) due to inflammatory adhesions 33521
ulcer of (duodenum), 33352
volvulus of 33451
Intoxication vitamin D, 33071
Jaw, fibrosarcoma of 33092
Kidney amyloid degeneration of 33021
calcification of, metastatic, 33071
carcinoma of (pelvis) papillary 33212
squamous-cell (with nephrolithiasis) extension into psoas muscle, 33471
necrosis of, diffuse (renal cortex) secondary 33181
sclerosis, nephro- 33481
arteriolar, 33231
tumor of, Wilms's, 33242
(See also Nephritis, Nephrolithiasis and Nephrosis)
Knee, chondroma of, 33041
Leishmaniasis of colon descending 33392
of esophagus 33252
Liver, abscesses of multiple 33282
amyloid degeneration of 33021
carcinoma of, metastatic (epidermoid) primary source undetermined, 33072
cirrhosis of, alcoholic type 33331 33352, 33411
hepatitis, infectious acute, 33361
hepatoma, with invasion of cystic duct and metastases to third lumbar vertebra 33441
lymphoma of lymphohistiocytic, 33292
Lung actinomycosis of, 33052
carcinoma of, adeno-, metastatic renal-cell, 33017
squamous-cell 33372, 33432
embolism of, 33491
embolism of multiple, 33301
hemangioma of, cavernous 33251
hemorrhages in 33322
infarct of, 33301
pneumonia organizing 33342
pneumonitis chronic, 33342
tuberculosis of, chronic, 33051, 33452
miliary, 33071
Lymphoma, malignant, Hodgkin's sarcoma type, of retroperitoneal lymph nodes, 33071
lymphoblastic, of small bowel appendix gall bladder liver mediastinum, retroperitoneal tissues and bone marrow 33292
Mediastinum lymphoma of, lymphoblastic, 33292
Meningioma of spinal cord 33442
Meningitis tuberculous 33071
Mesothelioma of pleura and pericardium, 33111
Muscle, dystrophy of pseudohypertrophic, 33311
Myocardium see Heart
Necrosis diffuse, of renal cortex secondary 33181
Nephritis, glomerulo- acute, 33342
chronic, 33022
subacute, 33482
pyelo-, 33381
Nephrolithiasis 33471
Nephrosis hemoglobinuric, 33191
idiopathic, 33372
lipoid acute, 33101
Oligodendroglioma (?) of brain, 33081
Ovary, oophoritis and paroophoritis, acute, 33521
chronic 33162
Pancreas, carcinoma of 33491
adeno- with metastases to liver 33172
with extension into and ulceration of stomach 33472
cyst of 33321
Pancreatitis, chronic with extension to wall of stomach 33102
Papilloma basal-cell of bronchus, with cornification, 33151
Periarthritis nodosa 33181 33241 33382
Pericardium mesothelioma 33111
pericarditis acute tuberculous 33391
Pentostin, general, 33312
tuberculous 33431
Pituitary body calcification of metastatic 33071
Pneumonia see Lung
Pneumonitis see Lung
Polymyositis, bulbar, 33011
Polynucleosis, porphyria, 33031
Prostate carcinoma of with metastases to spine, 33492
Rectum, see Intestine
Retroperitoneum neurofibrosarcoma of 33332
Rib tumor of, Ewing's, 33401
Sarcoidosis 33412
Sarcoma (?) of endometrium 33221
of jaw (fibro-), 33092
of retroperitoneal tissues (neurofibro-) 33332
of scapular region (fibromyx-), 33141
Scleritis coronary, 33022 33061
Sinusitis acute, ethmoid and sphenoid, 33082
Spinal cord, meningioma of 33442
poliomyelitis bulbar 33011
Spine tumor of (coccyx and sacrum) benign giant-cell, 333141
Spleen amyloid degeneration of, 33021
hypertrophy of 33372
Stomach adenocarcinoma of 33192
carcinoma of multiple polypoid 33171
extension of chronic pancreatitis to wall of 33102
ulcer benign peptic, 33271, 33351
with perforation 33312
Thyroid gland amyloid disease of 33281 33452
carcinoma of giant-cell type, 33512
Toe Ewing's tumor of, 33401
Tuberculosis of lung, chronic, 33051 33452
miliary, 33071
Tuberculous pericarditis acute and chronic, 33391
Tuberculous peritonitis 33431
Tumor Ewing's, of rib and toe, 33401
of fibula 33161
giant-cell (see Bone)
Wilms's of kidney 33242
Ulcer of duodenum, with erosion of pancreaticoduodenal artery 33352
of esophagus 33501
of stomach, benign peptic, 33271 33351
with perforation and mesenteric abscess, 33332
Uterus, cervix, cicatrix of, post radiation with stenosis of cervical canal 33462
endometrium, sarcoma of (?) 33221
endometrial stromal (endolymphatic fibromyosarcoma) (?) 33221
hematometrium of 33402
Vein, erosion of (intrahepatic branch of portal) with hemorrhage 33042
Vertebra, chordoma of, third lumbar 33032
Vitamin D intoxication, 33071
Volvulus of ileum 33451
Wilms's tumor of kidney 33242

SPEAKERS IN DISCUSSION OTHER THAN TRACY B. MALLORY

The numbers in heavy type refer to cases in which the speaker has presented the Differential Diagnosis
